Entered according to Act of Congress, in the year 1914, by the AMERICAN SOCIETY OF CIVIL ENGINEERS, in the office of the Librarian of Congress, at Washington.

American Society of Civil Engineers

OFFICERS FOR 1914

President, HUNTER McDONALD

Vice-Presidents

Term expires January, 1915:	*Term expires January, 1916:*
J. WALDO SMITH	CHARLES F. LOWETH
CHARLES H. RUST	GARDNER S. WILLIAMS

Secretary, CHARLES WARREN HUNT

Treasurer, JOHN F. WALLACE

Directors

Term expires January, 1915:	*Term expires January, 1916:*	*Term expires January, 1917:*
LINCOLN BUSH	JAMES H. EDWARDS	GEORGE W. FULLER
T. KENNARD THOMSON	HENRY W. HODGE	ARTHUR S. TUTTLE
*ROBERT A. CUMMINGS	LEONARD METCALF	CHARLES H. KEEFER
WILLIAM CAIN	HENRY R. LEONARD	MORTIMER E. COOLEY
E. C. LEWIS	EDWARD H. CONNOR	EUGENE E. HASKELL
W. A. CATTELL	SAMUEL H. HEDGES	RICHARD MONTFORT

Assistant Secretary, T. J. McMINN

Standing Committees

(THE PRESIDENT OF THE SOCIETY IS *ex-officio* MEMBER OF ALL COMMITTEES)

On Finance:	*On Publications:*	*On Library:*
LINCOLN BUSH	JAMES H. EDWARDS	J. WALDO SMITH
HENRY W. HODGE	WILLIAM CAIN	T. KENNARD THOMSON
LEONARD METCALF	ARTHUR S. TUTTLE	E. C. LEWIS
*ROBERT A. CUMMINGS	HENRY R. LEONARD	M. E. COOLEY
GEORGE W. FULLER	GARDNER S. WILLIAMS	CHAS. WARREN HUNT

Special Committees

ON CONCRETE AND REINFORCED CONCRETE: Joseph R. Worcester, J. E. Greiner, W. K. Hatt, Olaf Hoff, Richard L. Humphrey, Robert W. Lesley, Emil Swensson, A. N. Talbot.

ON ENGINEERING EDUCATION: Desmond FitzGerald, Onward Bates, D. W. Mead.

ON STEEL COLUMNS AND STRUTS: Austin L. Bowman, James H. Edwards, Charles F. Loweth, Rudolph P. Miller, Ralph Modjeski, Frank C. Osborn, George H. Pegram, Lewis D. Rights, George F. Swain, Emil Swensson, Joseph R. Worcester.

ON MATERIALS FOR ROAD CONSTRUCTION: W. W. Crosby, A. W. Dean, H. K. Bishop, A. H. Blanchard, George W. Tillson, Nelson P. Lewis, Charles J. Tilden.

ON VALUATION OF PUBLIC UTILITIES: Frederic P. Stearns, Charles S. Churchill, Leonard Metcalf, William G. Raymond, Henry E. Riggs, Jonathan P. Snow, William J. Wilgus.

TO INVESTIGATE CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINEERS: Nelson P. Lewis, S. L. F. Deyo, Dugald C. Jackson, William V. Judson, George W. Tillson, C. F. Loweth, John A. Bensel.

TO CODIFY PRESENT PRACTICE ON THE BEARING VALUE OF SOILS FOR FOUNDATIONS, ETC.: Robert A. Cummings, Edward C. Shankland, Edwin Duryea, Jr., James C. Meem, Walter J. Douglas, Samuel T. Wagner, Frank M. Kerr.

ON A NATIONAL WATER LAW: F. H. Newell, George G. Anderson, Charles W. Comstock, Clemens Herschel, W. C. Hoad, Robert E. Horton, John H. Lewis, Charles D. Marx, Gardner S. Williams.

ON FLOODS AND FLOOD PREVENTION: C. McD. Townsend, John A. Bensel, T. G. Dabney, C. E. Grunsky, Frank M. Kerr, Morris Knowles, J. B. Lippincott, Daniel W. Mead, John A. Ockerson, Arthur T. Safford, Charles Saville, F. L. Sellew.

TO REPORT ON STRESSES IN RAILROAD TRACK: A. N. Talbot, A. S. Baldwin, J. B. Berry, G. H. Bremner, John Brunner, W. J. Burton, Charles S. Churchill, W. C. Cushing, Robert W. Hunt, George W. Kittredge, C. G. E. Larsson, William McNab, G. J. Ray, F. E. Turneaure, J. E. Willoughby.

The House of the Society is open from 9 A. M. to 10 P. M. every day, except Sundays, Fourth of July, Thanksgiving Day, and Christmas Day.

HOUSE OF THE SOCIETY—220 WEST FIFTY-SEVENTH STREET, NEW YORK.

TELEPHONE NUMBER.....5913 Columbus.
CABLE ADDRESS.....“Ceas, New York.”

*Elected to fill the vacancy caused by the death of Emil Gerber, Director, on April 16th, 1914.

MINUTES OF MEETINGS

OF THE SOCIETY

November 18th, 1914.—The meeting was called to order at 8.30 P. M.; Vice-President J. Waldo Smith in the chair; Chas. Warren Hunt, Secretary; and present, also, 186 members and 30 guests.

A paper by S. W. Bowen, M. Am. Soc. C. E., entitled "The Design and Construction of Four Reinforced Concrete Viaducts at Fort Worth, Texas," which had been postponed from the meeting of October 21st, 1914, was presented for discussion.

A paper by J. H. Gandolfo, Assoc. M. Am. Soc. C. E., entitled "The Valuation of Public Utility Property," was presented by the Secretary, who also read a communication on the subject from Alex Dow, M. Am. Soc. C. E. The paper was discussed by Messrs. W. W. Crehore and F. Lavis.

A paper by John W. Alvord, M. Am. Soc. C. E., entitled "Fundamental Principles of Public Utility Valuation," was presented by the

author. The subject was discussed by Messrs. Alexander C. Humphreys, F. Lavis, L. L. Tribus, and Charles R. Harte.

Communications on the subject from Messrs. L. M. Haupt, L. L. Jewel, and Richard T. Dana, were not read on account of the lateness of the hour.

The Secretary announced the following deaths:

EDWARD COOK BURNS, of Jamestown, N. Y., elected Member, July 5th, 1882; died October 29th, 1914.

EMIL KUICHLING, of New York City, elected Member, September 3d, 1884; died November 9th, 1914.

Adjourned.

December 2d, 1914.—The meeting was called to order at 8.30 P. M.; Vice-President Gardner S. Williams in the chair; Chas. Warren Hunt, Secretary; and present, also, 136 members and 21 guests.

The minutes of the meetings of October 21st and November 4th, 1914, were approved as printed in *Proceedings* for November, 1914.

A paper by Minton M. Warren, Jun. Am. Soc. C. E., entitled "Penstock and Surge-Tank Problems" was presented by the author.

A paper by Raymond D. Johnson, Esq., entitled "The Differential Surge Tank" was presented by the author and illustrated with lantern slides.

The two papers were discussed orally by Messrs. John C. Trautwine, Jr., D. L. Webster, Minton M. Warren, and Raymond D. Johnson.

The Secretary presented by title discussions from Messrs. Roy Taylor and Irving P. Church.

The Secretary announced the election of the following candidates on December 2d, 1914:

AS ASSOCIATE MEMBERS

FREDERICK ABELS ALLNER, Baltimore, Md.
CARL ASHLEY, New York City
JOHN LELAND BECTON, Wilmington, N. C.
WILLIAM COOPER CAMPBELL, Columbus, Ga.
JOHN PEALE DE L'EAU, Betteravia, Cal.
GORDON HILDRETH FERNALD, Fitchburg, Mass.
HOWARD WASHINGTON HALL, Bisbee, Ariz.
GEORGE WILLIAM HARRIS, Port Arthur, Ont., Canada
NED ELMER HAWKINS, Youngstown, Ohio
LOUIS RICHARD HOWSON, Chicago, Ill.
EDWARD MELVILLE LYNCH, Glendale, Cal.
HARRY SEYMOUR MCKIBBEN, Warren, Ohio
GEORGE MAGUIRE, Baltimore, Md.
LESLIE WILLIAM MERRIMAN, Philadelphia, Pa.

CHANCEY SPENCER MILLARD, Vancouver, B. C., Canada
HARRY MONETT, Berkeley, Cal.
THOMAS BREW NOLAN, JR., Seattle, Wash.
RALPH WALDO PORTER, Pittsburgh, Pa.
WILLIAM REINHARDT, San Francisco, Cal.
JOHN CLEMENT REMINGTON, JR., Haddonfield, N. J.
PHILIP DURKEE RICE, San José, Cal.
ROBERT EARL RICHARDSON, Longmont, Colo.
JAY LA DREW SOUTHWORTH, Rome, N. Y.
WILLIS TILLMAN SPIVEY, Augusta, Ga.
MORRIS THOMPSON, Tampa, Fla.
LESSLIE RIELLE THOMSON, Montreal, Que., Canada
WILLIAM JACY TITUS, Indianapolis, Ind.
ROBERT OLANDO WHITEAKER, San Antonio, Tex.
JOSEPH FREMONT WILBER, Boston, Mass.
ADAM ZIEGLER, Tenafly, N. J.

AS ASSOCIATE

WILLIAM GREENE STONE, Utica, N. Y.

AS JUNIORS

WALTER SEIGFREID ANDERSON, Chicago, Ill.
ARTHUR JEROME BARZAGHI, New York City
GUY HERSEY BISHOP, Coon Rapids, Iowa
HOWARD FOSTER CLARK, San Francisco, Cal.
ROBERT MORRIS COPELAND, Kansas City, Mo.
WILLIAM GREENFIELD CORLETT, Oakland, Cal.
FRED WILBUR CROCKER, Portland, Ore.
ROBERT EDWARD DAKIN, New Haven, Conn.
DANIEL TALBOT FINKBEINER, Freeport, Pa.
NASRI SOLOMON FULEIHAN, Jerusalem, Palestine
LEONARD BRUCE GALLAGHER, Norristown, Pa.
HOMER ALLAN LESTER, Stanley, Va.
CONLAW ROBERT LYNCH, Newport, R. I.
KARL ANDREW MILLER, Meadville, Pa.
BURKE BROCKWAY ROBERTS, Cleveland, Ohio
LOUIS CLEMENT WAGNER, Houston, Tex.
JOHN MALCOLM WALLER, Kansas City, Mo.
CHARLES SMITH WHITNEY, New York City

The Secretary announced the transfer of the following candidates on December 2d, 1914:

FROM ASSOCIATE MEMBER TO MEMBER

DAVID REGINALD COOPER, New York City
CLARKE NIGHTINGALE KAST, Seattle, Wash.

FRANCIS FIELDING LONGLEY, New York City
RALPH DANFORD THOMAS, Minneapolis, Minn.
ERNEST WOODBURY WIGGIN, New Haven, Conn.

FROM JUNIOR TO ASSOCIATE MEMBER

ERNEST OSWALD BILLWILLER, Stockton, Cal.
JOHN JAMES CLARK, St. Louis, Mo.
HOWARD THOMPSON CRITCHLOW, Harrisburg, Pa.
WARREN ELLIS DAY, Salt Lake City, Utah
JOHN WILLIAM HORTON, Sacramento, Cal.
BENJAMIN EARL JONES, Helena, Mont.
LEWIS THAYER KNISKERN, New York City
ALBERT AUGUST KRIEGER, Louisville, Ky.
ALEXANDER MISCHKE, Warsaw, Russia
VINCENT ROBERTS, New York City
TAOYUH CLARANCE SUN, Shanghai, China
CARL FELIX KILL-MAR VON BLÜCHER, Corpus Christi, Tex.
CHARLES WILLIAM WOODRUFF, Portland, Ore.

The Secretary announced the following deaths:

EDMUND JOB STEERE, of Providence, R. I., elected Member, October 1st, 1913; died July 18th, 1914.

LUCIAN ARNOLD TAYLOR, of Worcester, Mass., elected Member, November 4th, 1891; died November 19th, 1914.

Adjourned.

December 16th, 1914.—Because of the necessity of going to press with this number of *Proceedings* in advance of this meeting, the publication of its minutes must be deferred until January, 1915. Two papers have been set down for discussion: "Submerged Pipe Work at Portland, Oregon," by D. D. Clarke, M. Am. Soc. C. E.; and "History of Little Rock Junction Railway Bridge of the St. Louis, Iron Mountain and Southern Railway Company, Over the Arkansas River, at Little Rock, Arkansas, 1883-1914," by C. E. Smith, M. Am. Soc. C. E.

OF THE BOARD OF DIRECTION

(Abstract)

December 2d, 1914.—The Board met at 3.30 P. M.; President McDonald in the chair; Chas. Warren Hunt, Secretary; and present, also, Messrs. Cummings, Edwards, Endicott, Hodge, Leonard, Loweth, Montfort, Smith, Swain, Tuttle, and Williams.

A Committee was appointed to draft the Annual Report of the Board of Direction.

The Presidents of the thirteen Local Associations of Members of the Society having been invited to meet at about the time of the Annual Meeting for the purpose of discussing matters connected with those Associations so that there might be uniformity of action and a better understanding of their functions, the following was adopted:

"In view of the importance of this particular occasion, mileage will be allowed to the President of each Local Association (or his representative) who attends this Special Meeting."

Charles Warren Hunt was appointed one of the four representatives of this Society on the John Fritz Medal Board of Award to serve four years to fill the vacancy caused by the expiration of his term.

The resignations of 2 Members, 2 Associate Members, and 1 Associate were accepted to take effect December 31st, 1914, and the resignation of 1 Associate Member was accepted to take effect immediately.

Ballots for membership were canvassed, resulting in the election of 30 Associate Members, 1 Associate, 18 Juniors, and the transfer of 13 Juniors to the grade of Associate Member.

Five Associate Members were transferred to the grade of Member.

Applications were considered, and other routine business was transacted.

Adjourned.

ANNOUNCEMENTS

The House of the Society is open from 9 A. M. to 10 P. M., every day, except Sundays, Fourth of July, Thanksgiving Day, and Christmas Day.

FUTURE MEETINGS

January 6th, 1915.—8.30 P. M.—This will be a regular business meeting. A paper by Samuel Tobias Wagner, M. Am. Soc. C. E., entitled "The Water-Proofing of Solid Steel-Floor Railroad Bridges," will be presented for discussion.

This paper is printed in this number of *Proceedings*.

February 3d, 1915.—8.30 P. M.—A regular business meeting will be held, and a paper by R. C. Strachan, M. Am. Soc. C. E., entitled "Nomographic Solutions for Formulas of Various Types," will be presented for discussion.

This paper is printed in this number of *Proceedings*.

ANNUAL MEETING

The Sixty-second Annual Meeting will be held at the Society House, on Wednesday and Thursday, January 20th and 21st, 1915.

COMMITTEE OF ARRANGEMENTS.

J. S. LANGTHORN,
WALTER H. GAHAGAN, JOHN HAYS MYERS,
J. H. GRANBERY, CHARLES WARREN HUNT.

The Business Meeting will be called to order at 10 o'clock on Wednesday morning. The Annual Reports will be presented, officers for the ensuing year elected, members of the Nominating Committee appointed. Reports of Special Committees presented for discussion, and other business transacted.

An excursion will be arranged for the afternoon of Wednesday, and in the evening there will be a reception, with dancing, at the Hotel Astor. Thursday will be devoted to an all-day excursion, the details of which will be announced later; and on Thursday evening there will be a Smoker at the Society House.

SPECIAL MEETINGS

Meetings, for discussion of the Report of the Special Committee on Materials for Road Construction, will be held at 10 A. M. and 2 P. M. on Friday, January 22d, 1915 (the day following the close of the Annual Meeting of the Society).

PROGRESS REPORTS OF SPECIAL COMMITTEES

Progress Reports of the Special Committees on Materials for Road Construction, on Steel Columns and Struts, and on Conditions of Employment of, and Compensation of, Civil Engineers, are printed in this number of *Proceedings* with the Papers and Discussions.

SEARCHES IN THE LIBRARY

In January, 1902, the Secretary was authorized to make searches in the Library, upon request, and to charge therefor the actual cost to the Society for the extra work required. Since that time many searches have been made, and bibliographies and other information on special subjects furnished.

The resulting satisfaction, to the members who have made use of the resources of the Society in this manner, has been expressed frequently, and leaves little doubt that if it were generally known to the membership that such work would be undertaken, many would avail themselves of it.

The cost is trifling compared with the value of the time of an engineer who looks up such matters himself, and the work can be performed quite as well, and much more quickly, by persons familiar with the Library.

In asking that such work be undertaken, members should specify clearly the subject to be covered, and whether references to general books only are desired, or whether a complete bibliography, involving search through periodical literature, is desired.

In reference to this work the Appendices* to the Annual Reports of the Board of Direction for the years ending December 31st, 1906, and December 31st, 1910, contain summaries of all searches made to date.

In making a search it sometimes happens that references are found which are not readily accessible to the person for whom the search is made. In that case the material may be reproduced by photography, and this can be done for members at the cost of the work to the Society, which is small. This method is particularly useful when there are drawings or figures in the text, which would be very expensive to reproduce by hand.

PAPERS AND DISCUSSIONS

Members and others who take part in the oral discussions of the papers presented are urged to revise their remarks promptly. Written communications from those who cannot attend the meetings should be sent in at the earliest possible date after the issue of a paper in *Proceedings*.

* *Proceedings*, Vol. XXXIII, p. 20 (January, 1907); Vol. XXXVII, p. 28 (January, 1911)

All papers accepted by the Publication Committee are classified by the Committee with respect to their availability for discussion at meetings.

Papers which, from their general nature, appear to be of a character suitable for oral discussion, will be published as heretofore in *Proceedings*, and set down for presentation to a future meeting of the Society, and on these, oral discussions, as well as written communications, will be solicited.

All papers which do not come under this heading, that is to say, those which from their mathematical or technical nature, in the opinion of the Committee are not adapted to oral discussion, will not be scheduled for presentation to any meeting. Such papers will be published in *Proceedings* in the same manner as those which are to be presented at meetings, but written discussions only will be requested for subsequent publication in *Proceedings* and with the paper in the volumes of *Transactions*.

The Board of Direction has adopted rules for the preparation and presentation of papers, which will be found on page 429 of the August, 1913, *Proceedings*.

LOCAL ASSOCIATIONS OF MEMBERS OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS

San Francisco Association

The San Francisco Association of Members of the American Society of Civil Engineers holds regular bi-monthly meetings, with banquet, and weekly informal luncheons. The former are held at 6 P. M., at the Palace Hotel, on the third Friday of February, April, June, August, October, and December, the last being the Annual Meeting of the Association.

Informal luncheons are held at 12.15 P. M. every Wednesday, and the place of meeting may be ascertained by communicating with the Secretary of the Association, E. T. Thurston, Jr., M. Am. Soc. C. E., 713 Mechanics' Institute, 57 Post Street.

The by-laws of the Association provide for the extension of hospitality to any member of the Society who may be temporarily in San Francisco, and any such member will be gladly welcomed as a guest.

Colorado Association

The meetings of the Colorado Association of Members of the American Society of Civil Engineers (Denver, Colo.) are held on the second Saturday of each month, except July and August. The hour and place of meeting are not fixed, but this information will be furnished on application to the Secretary, Roger W. Toll, Assoc. M. Am. Soc. C. E., 700 Tramway Building, Denver, Colo. The meetings are usually preceded by an informal dinner. Members of the American Society of Civil Engineers will be welcomed at these meetings.

Weekly luncheons are held on Wednesdays, at 12.30 P. M., at the Albany Hotel.

Visiting members are urged to attend the meetings and luncheons.

(Abstract of Minutes of Meeting)

November 21st, 1914.—The meeting was called to order; President Vincent in the chair; Roger W. Toll, Secretary; and present, also, 21 members and guests.

A letter was read from the Secretary of the Society, inviting the Association to send a representative to attend a meeting of the Presidents of the Local Associations to be held in New York on January 20th-21st, 1915. On motion, the invitation was accepted, and the Executive Committee was instructed to take such action in the matter as it shall decide.

The Secretary announced that no meeting of the Association had been held during October.

A paper by H. W. Cowan, M. Am. Soc. C. E., on "The Reconstruction of the Union Depot in the City of Denver", was presented by the author, and the subject was generally discussed.

A vote of thanks was tendered Mr. Cowan for his interesting paper.

Adjourned.

Atlanta Association

The Atlanta Association of Members of the American Society of Civil Engineers was organized on March 14th, 1912. The Association holds its meetings at the University Club, Atlanta, Ga.

At the meeting of the Association on December 29th, 1913, the new Chairman, John Ruddle, M. Am. Soc. C. E., was installed, and Messrs. Park A. Dallis and G. R. Solomon were appointed members of the Executive Committee. T. P. Branch, Assoc. M. Am. Soc. C. E., was elected Secretary.

Baltimore Association

On May 6th, 1914, the Baltimore Association of Members of the American Society of Civil Engineers was organized, a Constitution adopted, and the following officers were elected: J. E. Greiner, President; Francis Lee Stuart, First Vice-President; L. H. Beach, Second Vice-President; Harry D. Williar, Jr., Secretary-Treasurer; and Messrs. H. D. Bush, B. T. Fendall, B. P. Harrison, Calvin W. Hendrick, Oscar F. Lackey, M. A. Long, and A. A. Thompson, Directors.

At its meeting of September 2d, 1914, the Board of Direction considered and approved the proposed Constitution of the Baltimore Association of Members of the American Society of Civil Engineers.

Louisiana Association

The Louisiana Association of Members of the American Society of Civil Engineers (New Orleans, La.) has been organized with the following officers: Frank M. Kerr, President; J. F. Coleman and W. B. Gregory, Vice-Presidents; A. M. N. Blamphin, Treasurer; and L. C. Datz, Secretary.

Northwestern Association

At its meeting of November 4th, 1914, the Board of Direction considered and approved the proposed Constitution of the Northwestern Association of Members of the American Society of Civil Engineers (St. Paul and Minneapolis, Minn.).

Philadelphia Association

The Philadelphia Association of Members of the American Society of Civil Engineers was organized on December 22d, 1913. The meetings of the Association are held at the Engineers' Club of Philadelphia, 1317 Spruce Street.

(Abstract of Minutes of Meetings)

October 5th, 1914.—President George S. Webster in the chair; W. L. Stevenson, Secretary; and present, also, 70 members, and a number of guests.

The Annual Reports of the Secretary and Treasurer were read and approved.

The principles embodied in the proposed plan for the federation of engineers of Philadelphia and vicinity, were approved by the Association.

The draft of an Act for Licensing Engineers in Pennsylvania, prepared by the Engineers' Commission in order to obtain expressions of opinion, was discussed, and the following motion was carried:

"That it is the sense of this meeting that it is undesirable and unnecessary to license engineers."

In order that the subject might be presented to the Association in the most complete manner before final action, the President was authorized to appoint two committees of three; one to submit arguments for, and the other against, the licensing of engineers, at an adjourned meeting to be held one week later.

Ballots were canvassed, and the following officers were elected for the ensuing year: President, Richard L. Humphrey; Vice-Presidents, F. Herbert Snow and William Hunter; Directors, John Sterling Deans, John W. Ledoux, Edgar Marburg, and H. S. Smith; Treasurer, S. M. Swaab; Secretary, W. L. Stevenson.

Hunter McDonald, President, Am. Soc. C. E., addressed the meeting on the subjects of the Federation of Engineering Societies and on the Licensing of Engineers.

Adjourned.

October 12th, 1914.—President Richard L. Humphrey in the chair; W. L. Stevenson, Secretary; and present, also, 27 members and guests.

Messrs. John A. Vogleson, Chairman, and F. W. Abbott, of the Committee to submit arguments in favor of the licensing of engineers (of which the third member was Harrison Souder, M. Am. Soc. C. E.), addressed the meeting.

Edgar Marburg, M. Am. Soc. C. E., Chairman of the Committee to submit arguments against the licensing of engineers, presented a report signed by himself and Messrs. Henry H. Quimby and S. M. Swaab, the other members of the Committee.

After a discussion of the two reports, the following motion was passed:

"That the action of the previous meeting be reaffirmed."

The President was authorized to appoint a Committee on Licensing Engineers to represent the Association at the hearing of the Engineers' Commission, to keep in touch with the movement, and, if deemed advisable, to appear before any legislative committees.

(In conformity with this action, President Humphrey appointed the following Committee: Edgar Marburg, Chairman, John Sterling Deans, John W. Ledoux, H. R. Leonard, Henry H. Quimby, S. M. Swaab, Edward B. Temple, Samuel Tobias Wagner, and Richard L. Humphrey, *ex-officio*. This Committee amplified the report of the Committee of Three which had submitted arguments against the licensing of engineers. This report was presented by the Committee to the Engineers' Commission at the public hearing in Philadelphia, on October 19th, 1914, and the Commission requested the Committee to submit a supplementary report enlarging on the constructive features of the original report.)

Adjourned.

October 26th, 1914.—President Richard L. Humphrey in the chair; W. L. Stevenson, Secretary; and present, also, 35 members.

The Committee on Licensing Engineers submitted a Supplementary Report as requested by the Engineers' Commission.

This report recommended the creation of a State Department of Public Works which shall be in charge of (1) the Civil Service Examination System, and (2) a Supervisory System of Plans and Inspection of Engineering Works, and in which shall be centralized such other matters relating to public engineering activities as may seem proper.

After discussion, the following motion was passed:

"That this meeting endorse the principles embodied in the supplementary report of the Committee on Licensing Engineers and approve its transmission to the Engineers' Commission of Pennsylvania."

Adjourned.

Portland, Ore., Association

On June 18th, 1913, the Portland, Ore., Association of Members of the American Society of Civil Engineers was organized, with the following officers: E. G. Hopson, President; W. S. Turner, First Vice-President; D. D. Clarke, Second Vice-President; G. B. Hegardt, Treasurer; and Charles J. McGonigle, Secretary.

St. Louis Association

At its meeting of October 7th, 1914, the Board of Direction considered and approved the proposed Constitution of the St. Louis Association of Members of the American Society of Civil Engineers.

The following officers have been elected: President, J. A. Ockerson; First Vice-President, Edward E. Wall; Second Vice-President, F. J. Jonah; Secretary-Treasurer, Gurdon G. Black. The meetings of the Association are held at the Engineers' Club Auditorium.

Seattle Association

At the Annual Meeting of the Association, held on January 26th, 1914, the following officers were elected for the ensuing year; Ernest B. Hussey, President; A. H. Fuller, Vice-President; and Carl H. Reeves, Secretary-Treasurer.

Southern California Association

The Southern California Association of Members of the American Society of Civil Engineers (Los Angeles, Cal.) holds regular bimonthly meetings, with banquet, on the second Wednesday of February, April, June, August, October, and December, the last being the Annual Meeting of the Association.

Informal luncheons are held at 12.15 P. M. every Wednesday, and the place of meeting may be ascertained from the Secretary of the Association, W. K. Barnard, M. Am. Soc. C. E., 515 Central Building, Los Angeles, Cal.

The by-laws of the Association provide for the extension of hospitality to any member of the Society who may be temporarily in Los Angeles, and any such member will be gladly welcomed as a guest at any of the meetings or luncheons.

Spokane Association

At its meeting of March 4th, 1914, the Board of Direction considered and approved the proposed Constitution of the Spokane Association of Members of the American Society of Civil Engineers.

The following officers have been elected: President, C. S. MacCalla; Vice-President, U. B. Hough; Second Vice-President, Morton Macartney; Secretary-Treasurer, A. D. Butler.

Texas Association

At its meeting of December 31st, 1913, the Board of Direction considered and approved the proposed Constitution of the Texas Association of Members of the American Society of Civil Engineers. The headquarters of the Association is Dallas, Tex.

PRIVILEGES OF ENGINEERING SOCIETIES EXTENDED TO MEMBERS OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS

Members of the American Society of Civil Engineers will be welcomed by the following Engineering Societies, both to the use of their Reading Rooms, and at all meetings:

American Institute of Mining Engineers, 29 West Thirty-ninth Street, New York City.

American Society of Mechanical Engineers, 29 West Thirty-ninth Street, New York City.

Architekten-Verein zu Berlin, Wilhelmstrasse 92, Berlin W. 66, Germany.

Associação dos Engenheiros Civis Portuguezes, Lisbon, Portugal.

Australasian Institute of Mining Engineers, Melbourne, Victoria, Australia.

Boston Society of Civil Engineers, 715 Tremont Temple, Boston, Mass.

Brooklyn Engineers' Club, 117 Remsen Street, Brooklyn, N. Y.

Canadian Society of Civil Engineers, 413 Dorchester Street, West, Montreal, Que., Canada.

Civil Engineers' Society of St. Paul, St. Paul, Minn.

Cleveland Engineering Society, Chamber of Commerce Building, Cleveland, Ohio.

Cleveland Institute of Engineers, Middlesbrough, England.

Dansk Ingeniorforening, Amaliegade 38, Copenhagen, Denmark.

Detroit Engineering Society, 46 Grand River Avenue, West, Detroit, Mich.

Engineers and Architects Club of Louisville, 1412 Starks Building, Louisville, Ky.

Engineers' Club of Baltimore, Baltimore, Md.

Engineers' Club of Minneapolis, 17 South Sixth Street, Minneapolis, Minn.

Engineers' Club of Philadelphia, 1317 Spruce Street, Philadelphia, Pa.

Engineers' Club of St. Louis, 3817 Olive Street, St. Louis, Mo.

Engineers' Club of Toronto, 96 King Street, West, Toronto, Ont., Canada.

Engineers' Society of Northeastern Pennsylvania, 415 Washington Avenue, Scranton, Pa.

Engineers' Society of Pennsylvania, 31 South Front Street, Harrisburg, Pa.

Engineers' Society of Western Pennsylvania, 2511 Oliver Building, Pittsburgh, Pa.

Institute of Marine Engineers, 58 Romford Road, Stratford, London, E., England.

Institution of Engineers of the River Plate, Calle 25 de Mayo 195, Buenos Aires, Argentine Republic.

Institution of Naval Architects, 5 Adelphi Terrace, London, W. C., England.

Junior Institution of Engineers, 39 Victoria Street, Westminster, S. W., London, England.

Koninklijk Instituut van Ingenieurs, The Hague, The Netherlands.

DONATIONS*

THE REGULATION OF RIVERS.

By J. L. Van Ornum, M. Am. Soc. C. E. Cloth, 9½ x 6¼ in., illus., 10 + 393 pp. New York and London, McGraw-Hill Book Company, Inc., 1914. $4.00.

In this book, it is stated, the different methods of river regulation and improvements and their particular applicability to the varying conditions of such waterways, are discussed in detail, as well as the fundamental and scientific principles underlying such work, and in order to secure a more complete knowledge of the scientific laws involved, the author has presented quite fully the methods and results of experimental investigations and other propositions. He has assumed, it is said, a prior knowledge of Surveying and Hydraulics, and, therefore, the discussion of such introductory features includes only those topics necessary to an adequate comprehension of the whole subject. Figures, statistics, plans, and operations have been summarized, it is stated, or representative types have been given to illustrate and elucidate the fundamental principles involved. Many references are also given in the text and in foot-notes to books and papers which may be used as collateral reading on the subject. The Chapter headings are: Introduction; Commercial Considerations; General Phenomena; Investigations, Surveys, etc.; Methods of River Improvement; The Principles of Regulation; Works of Channel Contraction; The Protection of Erodible Banks; Dredging; Levees; The Control of the Current; Index.

POLYPHASE CURRENTS.

By Alfred Still. Second Edition, Revised. Cloth, 7¾ x 5 in., illus., 12 + 300 pp. New York, The Macmillan Co.; London, Whittaker & Co., 1914. $1.50.

The author states in the preface to this edition that the scope and viewpoint of the subject have not been changed, the object being to present the principles underlying the operation of polyphase currents in clear and simple terms. The book is intended, it is said, primarily for the student and user who may have to lay out and work out a complete polyphase scheme, exact details of machinery, etc., being omitted. The treatment of the subject is non-mathematical, it is stated, but extensive use has been made of graphical methods. The original matter has been rearranged, rewritten, and some of it entirely omitted as deemed necessary, the assumption still being held that the student is unfamiliar with alternating currents. All the figures and diagrams are said to have been redrawn, and all vector diagrams have been reversed to accord with the internationally agreed convention regarding leading and lagging vectors, and the symbols used to denote certain physical quantities have been changed for the same reason. The Chapter headings are: Elementary Study of Alternating Currents; Self-Induction and Capacity; Polyphase Currents: General Principles and Synchronous Generators; Measurement and Calculation of Power on Polyphase Circuits; Polyphase Transformers; Power Transmission by Polyphase Currents; Polyphase Induction Motors; Synchronous Generators, Frequency Converters, Compensated Induction Motors, and Rotary Converters; Appendix I, On the Relation Between Magnetic Flux and Induced E. M. F. in a Circuit Conveying an Alternating Current; Appendix II, Method of Drawing the Complete Vector Diagram for a Polyphase Induction Motor from Three Sets of Measurements Made on the Machine; Index.

SURGE TANK PROBLEMS:

An Investigation of Surge Tank Regulation Determining by Graphical and Analytical Methods Proper Solutions of Problems Created by Long Pipe Lines. By Franz Prasil. Authorized Translation by E. R. Weinmann and D. R. Cooper, Assoc. M. Am. Soc. C. E. Paper, 12 x 9 in., illus., 27 pp. Toronto, The Canadian Engineer; New York, E. R. Weinmann, 1914. 50 cents. (Donated by E. R. Weinmann.)

This paper includes, it is stated, a discussion of the problems leading to the determination of the dimensions and the development of methods, partly analytical and partly graphical, involved in the solution of these problems, on the assumption

* Unless otherwise specified, books in this list have been donated by the publishers.

that the main conduit from the intake to the surge tank consists of a pipe or tunnel running full under pressure. The translators have added a short bibliography on surge tank regulation which is printed at the end of the paper. The Contents are: Introduction; Derivation of Principal Equations; Special Cases; Investigation of the Influence of $h = U.V^2$; Conclusions; Appendix A, Surge Tank with Variable Cross-Section; Appendix B, Simplified and Approximate Formula for the Determination of Surge Tanks with Constant Cross-Section; Bibliography.

STRUCTURAL DESIGN:

Volume II, Design of Simple Structures. By Horace R. Thayer, Assoc. M. Am. Soc. C. E. Cloth, 9 x 6 in., illus., 9 + 495 pp. New York, D. Van Nostrand Company, 1914.

In the first volume of this series, the author discussed the elements of structural design. In this, the second volume, which presupposes, it is stated, a knowledge of mechanics, stresses, and the mathematics on which they depend, he has considered the design of such simple structures as beams, girders, viaducts, trusses, buildings, stand-pipes, and elevated tanks. An attempt, it is said, has been made to discuss these subjects from both the theoretical and practical standpoints, to which end a short bibliography of related works is given at the end of many of the subjects discussed, and many concrete examples are included. The Contents are: Beam Bridges, Plate Girders; Steel Viaducts and Elevated Railroads; Simple Riveted Truss Bridges; Simple Pin-Connected Bridges; Steel Mill Buildings; High Office Buildings; Miscellaneous Building Work; Stand-Pipes and Elevated Tanks; Index.

PRACTICAL RATE MAKING AND APPRAISEMENT.

By William D. Marks. Cloth, 7½ x 5 in., illus., 269 pp. South Hadley, Mass., Office, President's House, 1914. $2.00. (Donated by Jeannette Marks.)

The author's aim in this work, it is stated, is to be entirely practical and as brief as a discussion of the subject will permit. He has made many valuation reports and appraisements, it is said, and in this book gives a recapitulation of the more extended ones, including their objects, costs, and the local peculiarities connected with them. A few of his briefer reports are reproduced in full, and these are followed by a general discussion of the principles involved in the rate making and appraisement, with practical examples of their application. The Contents are: General Considerations; Report Upon Gas Rates and Prices for the City of Spokane, 1913; Report Upon the Fair and Reasonable Price of a 6.6 Ampere Magnetite Arc Light per Year, Minneapolis, 1911; Quantity Rates for Electricity; Methods of Appraisement; Present Value, Structural Cost of Reproduction, Original Cost, Structural Cost of Reduplication; Overhead Charges; Depreciation; Comparative Appraising; Market Value, English Going Value; Franchise Value; Present Value of Prospective Profits, Goodwill; Development Expense, Going Value, Intangible Values, Options; Books and Accounts, Operating Expenses and Income; The Law of Demand for Electricity, Reduction of Price Increases Profits; Gas Sales per Capita, Verification of Law of Demand; The London Sliding Scale, Marks' Dividing Scale; Capitalization, Assets and Profits of Massachusetts Gas Companies.

SURVEYING MANUAL

Designed for the Use of First-Year Students in Surveying and Especially for the Use of Non-Civil Engineering Students. By Howard Chapin Ives, Assoc. M. Am. Soc. C. E. Morocco, 7 x 4½ in., illus., 8 + 296 pp. New York, John Wiley & Sons, Inc.; London, Chapman & Hall, Limited, 1914. $2.25.

The preface states that although this Manual was designed as a field guide for first-year students in surveying, it is particularly adapted to the needs of mechanical, electrical, and chemical engineers and of students in agriculture and architecture as well as those in secondary schools. The subject-matter includes descriptions of the various instruments used in surveying and the methods of conducting surveys for various purposes, which are followed by problems relating to the subjects discussed, worked out in detail. Sample field notes reproduced at the same scale as those contained in regular field books and a set of tables sufficient for the ordinary work of surveying, are also included. The Chapter headings are: General Instructions; The Chain and Tape; The Level; The Compass; The Transit; Topographical Surveying; The Plane Table and the Sextant; The Aneroid Barometer and the Planimeter; Railroad Curves; The United States System of Laying Out the Public Lands; Computations; Plotting; Latitude, Longitude, and Azimuth; Large Surveys; Tables; Index.

CONCRETE-STEEL CONSTRUCTION:

Part I—Buildings: A Treatise Upon the Elementary Principles of Design and Execution of Reinforced Concrete Work in Buildings. By Henry T. Eddy, and C. A. P. Turner, M. Am. Soc. C. E. Cloth, 9½ x 6½ in., illus., 15 + 438 pp. Minneapolis, 1914. $6.00. (Donated by C. A. P. Turner.)

As stated in the secondary title, this volume is devoted to a discussion of the elementary principles and practical problems presented by construction work in reinforced concrete. An endeavor has been made, it is stated, to bring out the mechanics of reinforced concrete and to discuss in detail the questions of relative arrangement and disposition of materials in accordance with fixed principles of physics and mechanics, in order that rational rules may be more generally adopted for the safe and economic design of this type of construction. Patented as well as unpatented types are included in order, it is said, that the engineer may familiarize himself with the analysis of the former as well as that of the latter. The requirements of economy in the arrangement and dissemination of the reinforcement are also said to be discussed in considerable detail. The Chapter headings are: Introductory; General Types of Concrete Floor Construction; Beams; Beam Action and Slab Action Compared Through Application of the Laws of Bond Shear and the Theory of Work; Theory of Flat Slabs; Computed Stresses and Deflections Verified by Tests; Moments in Two-Way and Four-Way Flat Slabs; Reinforced Concrete Columns; Foundations; Elements of Economic Construction and Cost of Reinforced Concrete Work; Fireproof Properties of Concrete, etc.; Protection of Steel and Iron from Corrosion by Portland Cement, etc.; Floor Finish, etc.; Artistic and Commercially Practicable Concrete Surface Finishes; The Execution of Work, etc.; Index.

JOHNSON, LUCIEN SAMUEL. U. S. Asst. Engr., U. S. Engr. Office, Frankfort, Ky.

JORDÁN, RICARDO TOMÁS. Calle 67, Num. 519, Mérida, Yuc., Mexico.

LAYFIELD, ELWOOD NORMAN. 513 Transportation Bldg., Chicago, Ill.

MCKIM, JAMES ARTHUR. General Delivery, El Paso, Tex.

MANN, JOHN LAROY. 51 Chambers St., New York City.

MEMBERS (*Continued*)

MEARS, FREDERICK. First Lieut., Cav.; Member, Alaskan Eng. Comm., Care, Dept. of the Interior, Washington, D. C.

MENDIOLA, MANUEL MARIA. 4ª Calle de Tabasco 106, City of Mexico, Mexico.

MORSE, ROBERT BROOKS. Chf. Engr., Maryland State Dept. of Health, 16 West Saratoga St., Baltimore, Md.

POLHAMUS, ROYAL ALBERT. 1434 East 65th Pl., Chicago, Ill.

RICE, GEORGE STAPLES. Cons. Engr., 50 Court St., Brooklyn, N. Y.

RICHARDSON, JOSHUA WILSON. Contr. and Engr. (Richardson & Williams), 847 Equitable Bldg., Baltimore, Md.

SAFFORD, EDWARD STANLEY. Cons. Engr., Sharon, Mass.

SHEPLEY, CHARLES ROGERS. Engr. and Supt. of Constr., Emerson-Brantingham Co., 1540 Laurel Ave., St. Paul, Minn.

SIBERT, WILLIAM LUTHER. Lt.-Col., Corps of Engrs., U. S. A., P. O. Box 716, Cincinnati, Ohio.

SIDENIUS, HARRY. 306 Twenty-fifth Ave., West, Calgary, Alberta, Canada.

SMITH, GILMAN WALTER. Div. Erecting Mgr., Am. Bridge Co. of New York, 208 South La Salle St., Room 1392, Chicago, Ill.

SMOOT, LLOYD DUVALL. Commr. of Public Works, Engineers' Bldg., Jacksonville, Fla.

SPERRY, HENRY MUHLENBERG. Mgr., Dept., Publicity and Education, Gen. Ry. Signal Co., 108 Rugby Ave., Rochester, N. Y.

STORRS, HARRY ASAHEL. Cons. Engr., Tucson, Ariz.

SUNDSTROM, ALFRED YNGVE. Care, Albert B. Hager, 50 Church St., New York City.

SUTTON, CHARLES WOOD. Columbia Univ., New York City.

WADHAMS, JOSEPH PALMER. Care, McHenry & Murray, Second National Bank Bldg., New Haven, Conn.

WAUGH, WILLIAM HAMMOND. Div. Engr., Bureau of Public Works, Manila, Philippine Islands, 920 Berger Bldg., Pittsburgh, Pa.

WEAKLAND, FRANCIS LEE. 2659 B St., San Diego, Cal.

WILSON, HENRY WILLIAM. 1409 Commonwealth Bldg., Philadelphia, Pa.

ASSOCIATE MEMBERS.

ALBERT, DANIEL WESLEY. Supt., South Yuba Min. & Development Co., Washinton, Cal.

ANDERSON, ROBERT HARLOW. Res. Engr., J. G. White & Co., Inc., Emf, Polk County, Tenn.

BEATY, ROBERT ERNEST. 53 Washington Sq., South, New York City.

BERG, JOHN. Draftsman, Ralph Modjeski, 740 North Lotus Ave., Chicago, Ill.

BLOOD, CHARLES FREDERICK. Engr. and Contr., Morsemere, N. J.

BORCHERS, PERRY ELMER. 316 South 7th St., North Yakima, Wash.

BORDEN, GUY. 130 West 71st St., New York City.

BROOKS, MILES ELIJAH. 19 Milford St., Boston, Mass.

BURNS, WALTER ELLIOTT. 1255 East 21st St., Portland, Ore.

ASSOCIATE MEMBERS (*Continued*)

BUSHNELL, HOWARD EMORY. 32 Broadway, New York City.

CARHART, FRANK MILTON. Care, Southern Idaho Water Power Co., American Falls, Idaho.

CARPENTER, J C. Computer, Div. of Valuation, Interstate Commerce Comm., 170 Sixth Ave., Richmond Dist., San Francisco, Cal.

CHESLEY, FRANK EPHRAIM. 469 Corporation St., Beaver, Pa.

CHRISTIE, HANS LANGSTED. Care, Am. Bridge Co., Erecting Dept., Frick Bldg., Pittsburgh, Pa.

COLE, ERNEST DELEVAN. 1024 South Main St., Santa Ana, Cal.

CORNELL, JOHN WESLEY. Contr., 1311 Austin Ave., Waco, Tex.

CORNING, DUDLEY TIBBITS. 30 Belle Ave., Troy, N. Y.

COSCULLUELA Y BARRERAS, JUAN ANTONIO. Chf. Engr., Govt. Comm. for Drainage of Zapata Land, Calle D, Numero 10, Vedado, Havana, Cuba.

DAHLIN, JOHN EDWARD BARTHOLOMEW. Engr., Bridge Dept., C. & N. W. Ry., 6691 Olmstead Ave., Edison Park, Chicago, Ill.

DIETRICH, WILLIAM HENRY. With U. S. Steel Products Co., Care, Turnbulls (Glasgow), Ltd., No. 10, The Strand, Calcutta, India.

DRAKE, HENRY PHILKINS. Asst. Engr., Water Supply Comm. of Pennsylvania, Telegraph Bldg., Harrisburg, Pa.

ELLSWORTH, LINCOLN. 12 East 69th St., New York City.

ENTENMANN, PAUL MAX. 258 Harvard Boulevard, Los Angeles, Cal.

FOWLER, JAMES DUNCAN. Cons. Engr. (Koch & Fowler), 808 Sumpter Bldg., Dallas, Tex.

FRENCH, CARSON GEYER. Supt. of Constr., Gund Brewing Co., Cleveland, Ohio.

GOLDSMITH, WILLIAM. Supt., Municipal Asphalt Plant, Borough of Manhattan (Res., 508 West 142d St.), New York City.

GRAVES, GEORGE AUGUSTUS. Box 56, Morrisville, Pa.

HANAVAN, WILLIAM LAWRENCE. Asst. Engr., Board of Water Supply of New York City, 39 Academy St., Long Island City, N. Y.

HARLAN, CLARENCE HALLER. Contr. Engr., McClintic-Marshall Co., 210 Grant Ave., Millvale, Pa.

HARTRIDGE, EARLE MENELAS. Engr., Burchartz Fireproofing Co., 17 Battery Pl., New York City.

HENRY, DAVID EDWARD. 6234 Berlin Ave., St. Louis, Mo.

HILL, WILLIAM ANDREW. Care, Lockwood, Greene & Co., Salem, Mass.

HOPKINS, CHARLES ARCHER. Meeker, Colo.

HOWELL, FRANK SCOTT. Civ. Engr. in Chg., U. S. Immigration Station, Ellis Island, New York Harbor (Res., 21 Bancker Pl., New Rochelle), N. Y.

HUBER, WILLIAM THOMAS. Asst. Engr., New York State Comm. of Highways, 290 Summit Ave., Buffalo, N. Y.

HUNTER, WALTER GLADDEN. (Hunter & Morton), 210 Savings and Loan Bank Bldg., Stockton, Cal.

ASSOCIATE MEMBERS (*Continued*)

JONES, LEWIS ALLEN. U. S. Drainage Engr., Room 306, Federal Bldg., Montgomery, Ala.

JONES, WALTER ALPHEUS. Valuation Engr., N. S. R. R., Rochambeau Apartment No. 33, Norfolk, Va.

KANARY, MARK HENRY. Pres., Rock Island Bridge & Iron Co., 3125 Home Ave., Berwyn, Ill.

KNOUSE, HOMER VIRGIL. Const. Engr., Metropolitan Water Dist., City Hall, Omaha, Nebr.

LARSEN, HENRY AMBROSE. Structural Engr., 523 Northwestern Bank Bldg., Portland, Ore.

LETTON, HARRY PIKE. San. Engr., U. S. Public Health Service, 163 Dryades St., New Orleans, La.

LEWIS, WASHINGTON BART. 1712 Seventeenth St., Washington, D. C.

LYONS, HAROLD CHANDOS. Pres., Lyons & Doyle, Inc., 211 Central Ave., Flushing, N. Y.

MACK, EDWARD R. Supt. of Parks, 803 Washington St., Wilmington, Del.

MAGRUDER, FRANK CECIL. Belle Fourche, S. Dak.

METCALFE, JOSEPH DAVIS. Asst. Engr., Houston & Texas Central Ry., P. O. Box 165, West, Tex.

MORE, CHARLES CHURCH. Prof. of Civ. Eng., Univ. of Washington, 4309 Fourth Ave., N. E., Seattle, Wash.

MYERS, CHESTER JOHN. Asst. Engr., State Highway Comm., 239 Churchill Ave., Utica, N. Y.

NOLAN, SIMON FRANK. Engr. in Bridge and Harbor Dept. of City Engr.'s Office (Res., 16 University Ave.), Providence, R. I.

NUNN, HERBERT. Wheeldon Annex, Portland, Ore.

OKES, DAY IRA. Contr. (Hanlon & Okes), Minneapolis, Minn.

PAYNE, JAMES ELWOOD. Pres., The J. E. Payne Co., 704 Brunson Bldg., Columbus, Ohio.

PHELPS, HOWARD EASTWOOD. Asst. Prof. of Civ. Eng., Univ. of Colorado, 925 Grant Pl., Boulder, Colo.

PINNER, GUY. Chf. Insp., American Indemnity Co., Galveston, Tex.

ROBERTS, WILLIAM WILLIAMS, JR. Supt., Turner Constr. Co., P. O. Box 401, Salem, Mass.

ROBINSON, REUBEN TOTMAN. Res. Engr., Ohio River Bridge, C. & O. R. R., Box 519, Portsmouth, Ohio.

ROSE, WILLIAM HENRY. Capt., Corps of Engrs., U. S. A., Balboa Heights, Canal Zone, Panama.

SARGENT, JOSEPH ANDREWS. Care, John M. Plummer, Pearson Eng. Corporation, 115 Broadway, New York City.

SCHARSCHMIDT, SAMUEL HOWARD. 418 North 2d St., Elkhart, Ind.

SIMPSON, CHARLES RANDOLPH. Civ. and Hydr. Engr., 40 King St., Elizabeth, N. J.

STILES, ALBERT IRVINE. P. O. Box 9, Station J, New York City.

TOOPS, GEORGE NOBLE. Siloam Springs, Ark.

ASSOCIATE MEMBERS (*Continued*)

TRAVERS-EWELL, ANDREW. Southern Representative, Westinghouse, Church, Kerr & Co., 37 Wall St., New York City.

VAN SCOYOC, HARRY STEWART. Chf. Engr., Toronto-Hamilton Highway Comm., 49 Wellington St., East, Toronto, Ont., Canada.

VOORHEES, ISAAC SPURR. Asst. Engr., U. S. Reclamation Service, Box 214, Klamath Falls, Ore.

WARREN, HORACE PRETTYMAN. 345 North 34th St., Lincoln, Nebr.

WATSON, WALTER. 120 West Main St., Salem, Va.

WEINERT, FERDINAND JACOB FREDERICK. Chf. Engr., Banner Iron Works. 7619 Hiawatha Ave., Richmond Heights, St. Louis County, Mo.

WHITSIT, LYLE ANTRIM. Dist. Engr., Forest Service, Majestic Bldg., Denver, Colo.

WICKLINE, GEORGE GROVER. Bridge Engr., McLennan County, Care, County Engr., Waco, Tex.

WIGGINS, RALPH RAYMOND. 1002 Church St., Indiana, Pa.

WORLEY, ALBERT HARRISON. 3622 Garfield Ave., Kansas City, Mo.

ASSOCIATES

BELZNER, THEODORE. Insp. in Chg., 155th St., Viaduct, Dept. of Bridges (Res., 606 West 155th St.), New York City.

WILSON, HUGH MONROE. Vice-Pres. and Gen. Mgr., McGraw Pub. Co., Inc., 239 West 39th St. (Res., 375 Park Ave.), New York City.

JUNIORS

BANBROOK, HERRMANN. 105 Smith Ave., Detroit, Mich.

BEALL, PENDLETON. 40 Cannon St., Poughkeepsie, N. Y.

BLAINE, ELMER STYNER. Res. Engr., The Little River Drainage Dist. of Missouri, Parma, Mo.

BOIG, ALEXANDER FLETCHER. Care, Providence Steel & Iron Co., P. O. Box 812, Providence, R. I.

BOLIN, HARRY WILLIAM. 1620 Jordan St., Portland, Ore.

DRURY, WALTER RHODES. 1316 Beach St., Flint, Mich.

GIBBLE, ISAAC OBERHOLZER. With The Trussed Concrete Steel Co., 115 Broadway, Youngstown, Ohio.

GOODFELLOW, JAMES GORDON. General Delivery, Chief Post Office, London, England.

GOODRICH, THOMAS MACLENATHAN. Chf. Engr., Canadian Standard Concrete Steel Co.; Chf. Engr., Standard Concrete Steel Co. of Illinois, 123 West Madison St., Room 1200, Chicago, Ill.

GUISSINGER, JOHN ADAM. Abbeville, Miss.

KELLERSBERGER, ARNOLD CHARLES. Houston Heights, Tex.

KRACH, FRED ROY. Surv., U. S. Engr. Office, R. R. No. 2, U. S. Eng., Le Clair, Iowa.

LEMCKE, KARL WOLFGANG. 411 Park Ave., Mechanicsville, N. Y.

JUNIORS (*Continued*)

MAYPER, VICTOR. Eng. Draftsman, Public Service Comm., First Dist., State of New York, 2011 Morris Ave., New York City.

REDLIEN, WILLIAM HENRY. 144 Maple St., Richmond Hill, N. Y.

RINDSFOOS, CHARLES SIESEL. (The U. S. Purchasing Corporation), Woolworth Bldg., New York City.

ROSSI, IRVING. Structural Draftsman, Milliken Bros., Inc., 88 Summit Ave., Jersey City, N. J.

SCHEDLER, CARL WILLIAM, JR. 211 Third St., Niagara Falls, N. Y.

SMITH, WILLIAM DURKEE. 4126 Twelfth Ave., N. E., Seattle, Wash.

STARKWEATHER, ALFRED KENNETH. Asst. Engr., Passaic Val. Sewerage Comm., 16 Holmes St., Nutley, N. J.

STREET, JOHN ZADOK. Care, U. S. Reclamation Service, Fort Shaw, Mont.

STROHL, RICHARDS MERLE. Asst. Engr., St. John's Levee and Drainage Dist. of Missouri; Prin. Asst. Engr., The Berthe Co., Jonesboro, Ark.

RESIGNATIONS

ASSOCIATE MEMBER

	Date of Resignation.
THON, GEORGE LOUIS	Nov. 4, 1914

ASSOCIATE

AUCHINCLOSS, JOHN WINTHROP	Nov. 4, 1914

JUNIOR

BREWER, WILLARD SEYMOUR	Nov. 13, 1914

DEATHS

BURNS, EDWARD COOK. Elected Member, July 5th, 1882; died October 29th, 1914.

KUICHLING, EMIL. Elected Member, September 3d, 1884; died November 9th, 1914.

TAYLOR, LUCIAN ARNOLD. Elected Member, November 4th, 1891; died November 19th, 1914.

Total Membership of the Society, December 3d, 1914, 7 683.

MONTHLY LIST OF RECENT ENGINEERING ARTICLES OF INTEREST

(November 3d to December 1st, 1914)

NOTE.—*This list is published for the purpose of placing before the members of this Society, the titles of current engineering articles, which can be referred to in any available engineering library, or can be procured by addressing the publication directly, the address and price being given wherever possible.*

LIST OF PUBLICATIONS

In the subjoined list of articles, references are given by the number prefixed to each journal in this list:

(1) *Journal*, Assoc. Eng. Soc., Boston, Mass., 30c.
(2) *Proceedings*, Engrs. Club of Phila., Philadelphia, Pa.
(3) *Journal*, Franklin Inst., Philadelphia, Pa., 50c.
(4) *Journal*, Western Soc. of Engrs., Chicago, Ill., 50c.
(5) *Transactions*, Can. Soc. C. E., Montreal, Que., Canada.
(6) *School of Mines Quarterly*, Columbia Univ., New York City, 50c.
(7) *Gesundheits Ingenieur*, München, Germany.
(8) *Stevens Institute Indicator*, Hoboken, N. J., 50c.
(9) *Engineering Magazine*, New York City, 25c.
(11) *Engineering* (London), W. H. Wiley, 432 Fourth Ave., New York City, 25c.
(12) *The Engineer* (London), International News Co., New York City, 35c.
(13) *Engineering News*, New York City, 15c.
(14) *Engineering Record*, New York City, 10c.
(15) *Railway Age Gazette*, New York City, 15c.
(16) *Engineering and Mining Journal*, New York City, 15c.
(17) *Electric Railway Journal*, New York City, 10c.
(18) *Railway Review*, Chicago, Ill., 15c.
(19) *Scientific American Supplement*, New York City, 10c.
(20) *Iron Age*, New York City, 20c.
(21) *Railway Engineer*, London, England, 1s. 2d.
(22) *Iron and Coal Trades Review*, London, England, 6d.
(23) *Railway Gazette*, London, England, 6d.
(24) *American Gas Light Journal*, New York City, 10c.
(25) *Railway Age Gazette*, Mechanical Edition, New York City, 20c.
(26) *Electrical Review*, London, England, 4d.
(27) *Electrical World*, New York City, 10c.
(28) *Journal*, New England Water-Works Assoc., Boston, Mass., $1.
(29) *Journal*, Royal Society of Arts, London, England, 6d.
(30) *Annales des Travaux Publics de Belgique*, Brussels, Belgium, 4 fr.
(31) *Annales* de l'Assoc. des Ing. Sortis des Ecoles Spéciales de Gand, Brussels, Belgium, 4 fr.
(32) *Mémoires et Compte Rendu des Travaux*, Soc. Ing. Civ. de France, Paris, France.
(33) *Le Génie Civil*, Paris, France, 1 fr.
(34) *Portefeuille Economiques des Machines*, Paris, France.
(35) *Nouvelles Annales de la Construction*, Paris, France.
(36) *Cornell Civil Engineer*, Ithaca, N. Y.
(37) *Revue de Mécanique*, Paris, France.
(38) *Revue Générale des Chemins de Fer et des Tramways*, Paris, France.
(39) *Technisches Gemeindeblatt*, Berlin, Germany, 0, 70m.
(40) *Zentralblatt der Bauverwaltung*, Berlin, Germany, 60 pfg.
(41) *Electrotechnische Zeitschrift*, Berlin, Germany.
(42) *Proceedings*, Am. Inst. Elec. Engrs., New York City, $1.
(43) *Annales des Ponts et Chaussées*, Paris, France.
(44) *Journal*, Military Service Institution, Governors Island, New York Harbor, 50c.
(45) *Colliery Engineer*, Scranton, Pa., 25c.
(46) *Scientific American*, New York City, 15c.
(47) *Mechanical Engineer*, Manchester, England, 3d.
(48) *Zeitschrift*, Verein Deutscher Ingenieure, Berlin, Germany, 1, 60m.
(49) *Zeitschrift für Bauwesen*, Berlin, Germany.
(50) *Stahl und Eisen*, Düsseldorf, Germany.
(51) *Deutsche Bauzeitung*, Berlin, Germany.
(52) *Rigasche Industrie-Zeitung*, Riga, Russia, 25 kop.
(53) *Zeitschrift*, Oesterreichischer Ingenieur und Architekten Verein, Vienna, Austria, 70h.
(54) *Transactions*, Am. Soc. C. E., New York City, $12.
(55) *Transactions*, Am. Soc. M. E., New York City, $10.
(56) *Transactions*, Am. Inst. Min. Engrs., New York City, $6.

(57) *Colliery Guardian*, London, England, 5d.
(58) *Proceedings*, Engrs.' Soc. W. Pa., 2511 Oliver Bldg., Pittsburgh, Pa., 50c.
(59) *Proceedings*, American Water-Works Assoc., Troy, N. Y.
(60) *Municipal Engineering*, Indianapolis, Ind., 25c.
(61) *Proceedings*, Western Railway Club, 225 Dearborn St., Chicago, Ill., 25c.
(62) *Steel and Iron*, Thaw Bldg., Pittsburgh, Pa., 10c.
(63) *Minutes of Proceedings*, Inst. C. E., London, England.
(64) *Power*, New York City, 5c.
(65) *Official Proceedings*, New York Railroad Club, Brooklyn, N. Y., 15c.
(66) *Journal of Gas Lighting*, London, England, 6d.
(67) *Cement and Engineering News*, Chicago, Ill., 25c.
(68) *Mining Journal*, London, England, 6d.
(69) *Der Eisenbau*, Leipzig, Germany.
(71) *Journal*, Iron and Steel Inst., London, England.
(71a) *Carnegie Scholarship Memoirs*, Iron and Steel Inst., London, England.
(72) *American Machinist*, New York City, 15c.
(73) *Electrician*, London, England, 18c.
(74) *Transactions*, Inst. of Min. and Metal., London, England.
(75) *Proceedings*, Inst. of Mech. Engrs., London, England.
(76) *Brick*, Chicago, Ill., 20c.
(77) *Journal*, Inst. Elec. Engrs., London, England, 5s.
(78) *Beton und Eisen*, Vienna, Austria, 1, 50m.
(79) *Forscherarbeiten*, Vienna, Austria.
(80) *Tonindustrie Zeitung*, Berlin, Germany.
(81) *Zeitschrift für Architektur und Ingenieurwesen*, Wiesbaden, Germany.
(82) *Mining and Engineering World*, Chicago, Ill., 10c.
(83) *Gas Age*, New York City, 15c.
(84) *Le Ciment*, Paris, France.
(85) *Proceedings*, Am. Ry. Eng. Assoc., Chicago, Ill.
(86) *Engineering-Contracting*, Chicago, Ill., 10c.
(87) *Railway Engineering and Maintenance of Way*, Chicago, Ill., 10c.
(88) *Bulletin* of the International Ry. Congress Assoc., Brussels, Belgium.
(89) *Proceedings*, Am. Soc. for Testing Materials, Philadelphia, Pa., $5.
(90) *Transactions*, Inst. of Naval Archts., London, England.
(91) *Transactions*, Soc. Naval Archts. and Marine Engrs., New York City.
(92) *Bulletin*, Soc. d'Encouragement pour l'Industrie Nationale, Paris, France.
(93) *Revue de Métallurgie*, Paris, France, 4 fr. 50.
(95) *International Marine Engineering*, New York City, 20c.
(96) *Canadian Engineer*, Toronto, Ont., Canada, 10c.
(98) *Journal*, Engrs. Soc. Pa., Harrisburg, Pa., 30c.
(99) *Proceedings*, Am. Soc. of Municipal Improvements, New York City, $2.
(100) *Professional Memoirs*, Corps of Engrs., U. S. A., Washington, D. C., 50c.
(101) *Metal Worker*, New York City, 10c.
(102) *Organ für die Fortschritte des Eisenbahnwesens*, Wiesbaden, Germany.
(103) *Mining and Scientific Press*, San Francisco, Cal., 10c.
(104) *The Surveyor and Municipal and County Engineer*, London, England, 6d.
(105) *Metallurgical and Chemical Engineering*, New York City, 25c.
(106) *Transactions*, Inst. of Min. Engrs., London, England, 6s.
(107) *Schweizerische Bauzeitung*, Zürich, Switzerland.
(108) *Southern Machinery*, Atlanta, Ga., 10c.
(109) *Journal*, Boston Soc. C. E., Boston, Mass., 50c.
(110) *Journal*, Am. Concrete Inst., Philadelphia, Pa., 50c.
(111) *Journal of Electricity, Power and Gas*, San Francisco, Cal., 25c.

LIST OF ARTICLES

Bridges.

Opening Bridges over the Nile at Cairo.* Arthur James Knowles. (63) Vol. 196.
Renewal of Large-Span Girders in Southern India. Percy Rothera. (63) Vol. 196.
Bridge Substructures.* John W. Doty. (5) Vol. 28, Pt. 1.
St. Lawrence River Bridge. P. B. Motley. (5) Vol. 28, Pt. 1.
City and County Highway Drainage. (Culverts.) Frank Reed. (60) Nov.
Use and Development of the Ponton Equipage in the United States Army, with Special Reference to the Civil War. M. J. McDonough and P. S. Bond. (100) Nov.
The Colorado Street Bridge.* (60) Nov.

*Illustrated.

Bridges—(Continued).

Design, Construction and Detailed Labor Costs of the Substructure of the Double-Leaf Trunnion Bascule Bridge at Chicago Ave., Chicago, Ill.* Carl O. Johnson. (86) Nov. 4.
Two Striking Steel Bridges on the Lake Erie & Eastern R. R.* (13) Nov. 5.
Concrete Viaduct with 50-Ft. Walls.* (13) Nov. 5.
Concrete Highway Bridge Construction as Standardized by Iowa Commission.* C. B. McCullough. (14) Nov. 7.
Main Pedestals, Quebec Bridge.* H. P. Borden. (96) Nov. 12.
The Hoang Ho Bridge, China.* (19) Nov. 14.
Ultimate Strength of Carbon and Nickel-Steel Models of Quebec Bridge Members; Tension Tests of Reinforced Steel Plates and of Alternating Stress Members, and Compression Tests of Four Struts.* (14) Nov. 14.
Large Trussed Concrete Bridge, Structure of 182-Foot Span, with Parabolic Reinforced Concrete Compression Chord, Believed to be Longest of its Kind.* (14) Nov. 14.
Design and Construction of the Lower Ganges Bridge in India.* (86) Nov. 18.
Slate Creek Bridge, Building a Concrete Arch Bridge 56 Mi. from Rail.* Jean H. Knox. (13) Nov. 19.
Erecting the Snake River Viaduct: O.-W. R. R. & Nav. Co.* W. J. Howard. (13) Nov. 19.
The World's Longest Bascule Bridge.* Herbert T. Wade. (46) Nov. 21.
Design and Construction of the San Jacinto St. Reinforced Concrete Bridge, Houston, Texas.* (86) Nov. 25.
Shifting the Milwaukee River Drawbridge; C. & N. W. Ry.* (13) Nov. 26.
Conveying Concreting Material by Belts, at the Hell Gate Bridge.* (13) Nov. 26.
Main Span of Detroit-Superior Bridge over Cuyahoga River at Cleveland.* (14) Nov. 28.
Incasing Steel on Rock Island Bridge at Chicago.* (14) Nov. 28.
Schleppbahnbrücke aus Eisenbeton in Pöchlarn.* Hans Schäfer. (80) Sept. 26.

Electrical.

The Fire Hazard in Turbo-Generators. G. S. Lawler. (55) Vol. 35.
Discussion on High Tension Insulators (before the Canadian Soc. of Civ. Engrs.).* (5) Vol. 28, Pt. 1.
Automatic Voltage Regulators.* Chas. C. Garrard. (73) Serial beginning Oct. 30.
Reinforced Concrete Poles for San Francisco Municipal Railway.* John S. Martin. (67) Nov.
The Corona Produced by Continuous Potentials.* Stanley P. Farwell. (42) Nov.
Protective Reactors for Feeder Circuits of Large City Power Systems.* James Lyman, Leslie L. Perry, and A. M. Rossman. (42) Nov.
Use of Reactance with Synchronous Converters an Insurance to Continuity of Service and a Protection to Apparatus.* J. L. McK. Yardley. (42) Nov.
La Salle Plant Saves $45 000 Annually.* Thomas Wilson. (64) Nov. 3.
The Government Electric Power Station of Bangkok.* Francis B. Shaw. (26) Serial beginning Nov. 6.
On Atmosphere Refraction and Its Bearing on the Transmission of Electro-Magnetic Waves Round the Earth's Surface.* J. A. Fleming. (Abstract of paper read before the Physical Soc.) (73) Nov. 6.
The Telephone Plant with Relation to Fires.* W. D. Scott and G. P. Nock. (111) Nov. 7.
Air-Break Switches. W. P. Hammond. (From the *General Electric Review.*) (19) Nov. 7.
Seaview Hospital Plant.* A. D. Blake. (64) Nov. 10.
Electrical Instruments and Graphic Charts in Shop Operation.* C. E. Clewell. (72) Nov. 12.
The Law of Power-House Economy.* R. H. Parsons. (11) Nov. 13.
Radiotelegraphy in the Commonwealth of Australia.* J. G. Balsillie. (Paper read before the British Assoc.) (73) Nov. 13.
Substation for Seattle Municipal Railway.* H. J. Kennedy. (111) Nov. 14.
Wireless Telegraph and Wireless Telephone on the Union Pacific R. R.* (18) Nov. 14.
Use of Arc Lamps for Photographic Purposes.* V. A. Clarke. (27) Nov. 14.
A Method of Testing Instrument Transformers.* P. G. Agnew. (27) Nov. 21.
Centralization of Pittsburgh's Central Station Plants.* Charles C. Lynde. (62) Nov. 23.
West Breakwater Power Plant.* A. D. Williams. (64) Nov. 24.
Comparison of Radiation Quality of Filaments.* W. W. Coblentz. (27) Nov. 28.
Elektro-hydraulische Nietmaschinen schweizerischer Konstruktion.* (107) Oct. 24.
Synchron-Motorgenerator oder Einankerumformer?* Hugo Ring. (41) Nov. 5.
Kabelverlegung an der Felsenküste des Hardanger Fjords.* (41) Nov. 5.
Induktionszähler für einphasigen Wechselstrom, Form A T, der Danubia A.-G. in Strasburg i. Els.* (41) Nov. 5.

*Illustrated.

Marine.

Some Public Works at Kuching, Sarawak.* Harry Frederick Carew-Gibson. (63) Vol. 196.
The Evolution of the Battleship of the Dreadnought Type. W. A. Dobson. (2) Oct.
Shallow-Draught Steamer for the Yangtse Kiang.* (11) Nov. 6.
A Geared Turbine Atlantic Liner.* (12) Nov. 6.
The Japanese Navy.* (46) Nov. 7.
Mechanical Gear for Operating Boat-Davits.* (11) Nov. 20.
Wirelessly-Controlled Beacons.* H. Bannerman-Phillips. (46) Nov. 21.
New Dry Dock for San Francisco.* (13) Nov. 26.
Bulkheads for Boston Dry Dock.* (13) Nov. 26.
The Resistance to a Ship's Motion.* Hermann. (Translated from article in *Die Umschau.*) (19) Nov. 28.

Mechanical.

Standardization of Pipe Thread Gages.* (55) Vol. 35.
Cost of Upkeep of Horse-Drawn Vehicles against Electric Vehicles. W. R. Metz. (55) Vol. 35.
Practical Operation of Gas Engines Using Blast-Furnace Gas as Fuel.* Charles C. Sampson. (55) Vol. 35.
Notes on the Further Operation of Large Boilers of the Detroit Edison Company.* J. W. Parker. (55) Vol. 35.
Task Setting for Firemen and Maintaining High Efficiency in Boiler Plants.* Walter N. Polakov. (55) Vol. 35.
The Properties of Steam.* R. C. H. Heck. (55) Vol. 35.
Report on Hoisting and Conveying. (55) Vol. 35.
Dynamic Braking for Coal and Ore Handling Machinery. Clark T. Henderson. (55) Vol. 35.
Cotton Conveying Systems, Their Safeguards against Fire.* H. A. Burnham. (55) Vol. 35.
Efficiency of Rope Driving as a Means of Power Transmission.* E. H. Ahara. (55) Vol. 35.
Comparative Tests of Three Types of Lineshaft Bearings.* Carl C. Thomas, E. R. Maurer, and L. E. A. Kelso. (55) Vol. 35.
Pitot Tubes for Gas Measurement.* W. C. Rowse. (55) Vol. 35.
Tests of Vacuum Cleaning Systems.* J. R. McColl. (55) Vol. 35.
A New Process of Cleaning Producer Gas.* H. F. Smith. (55) Vol. 35.
Present Status of the Large Gas Engine in Europe.* P. Langer. (55) Vol. 35.
A Record of Pressed Fits. C. F. MacGill. (55) Vol. 35.
Cast Iron for Machine-Tool Parts.* Henry M. Wood. (55) Vol. 35.
Gears for Machine-Tool Drives. John Parker. (55) Vol. 35.
The Art of Enameling or the Coating of Steel and Iron with Glass. Raymond F. Nailler. (55) Vol. 35.
Tests upon the Transmission of Heat in Vacuum Evaporators.* E. W. Kerr. (55) Vol. 35.
Pulp and Newspaper Manufacture.* J. Stadler. (5) Vol. 28, Pt. 1.
The Electrical Driving of Winding Engines and Rolling Mills.* C. Anthony Ablett and H. M. Lyons. (5) Vol. 28, Pt. 1.
The Magnetic and Mechanical Properties of Manganese Steel.* R. A. Hadfield and B. Hopkinson. (71) Vol. 89.
The Recrystallisation of Deformed Iron.* C. Chappell. (71) Vol. 89.
Failures of Heavy Boiler Shell Plates.* Sidney A. Houghton. (71) Vol. 89.
The Hardening of Metals, with Special Reference to Iron and Its Alloys.* C. A. Edwards and H. C. H. Carpenter. (71) Vol. 89.
A Contribution to the Theory of Hardening.* Andrew M'Cance. (71) Vol. 89.
Some Recent Improvements in Case-Hardening Practice.* Henry L. Heathcote. (71) Vol. 89.
Forms in which Sulphides May Exist in Steel Ingots.* J. O. Arnold and G. R. Bolsover. (71) Vol. 89.
Cyclical Changes of Temperature in a Gas-Engine Cylinder.* Ernest George Coker and Walter Alfred Scoble. (63) Vol. 196.
The Problem of the Thrust Bearing.* Henry Thornton Newbigin. (63) Vol. 196.
Electrical Precipitation of Fumes and Smoke, and Smoke Monitors.* W. W. Strong. (98) Oct.
Babbitt and its Application. T. T. Johnston. (47) Oct. 23.
The Selection of Grinding Wheels for the Foundry.* Carl Frederick Dietz. (Paper read before the Am. Foundrymen's Assoc.) (47) Oct. 23.
General Melting Characteristics of Acid Steel for Castings. A. F. Stirling Blackwood. (Paper read before the Am. Foundrymen's Assoc.) (47) Serial beginning Oct. 30.
Combined Oil Furnace, Boiler and Drop Hammer Plant.* (12) Oct. 30.
Coal-Handling Plant at Southend-On-Sea Electricity Station.* (11) Oct. 30.

*Illustrated.

Mechanical—(Continued).

Autogenous Welding. C. L. Dickert. (From Report to the Inter. Ry. General Foremen's Assoc.) **(25)** Nov.
National Mortar & Supply Co.'s Plant.* **(67)** Nov.
Coal Gas Residuals.* Fred. H. Wagner. (Paper read before the Am. Gas Inst.) **(105)** Nov.; **(24)** Nov. 16.
The Use of Turbines for Various Purposes.* F. G. Cutler. (Paper read before the Am. Iron and Steel Inst.) **(62)** Nov. 2.
Powdered Coal for Heating Furnaces.* C. F. Herington. **(20)** Nov. 5.
Repair Department of Modern Steel Plant. John Hulst. (Paper read before the Am. Iron and Steel Inst.) **(20)** Nov. 5; **(62)** Nov. 2.
The Influence of Motor Drive on Machine Tool Design.* C. E. Clewell. **(72)** Nov. 5.
Refractories, Their Selection and Use in the Foundry. Walter H. Kelley. (Paper read before the Am. Foundrymen's Assoc.) **(47)** Nov. 6.
Semi-Portable Superheated-Steam Engine.* **(11)** Nov. 6.
Automobile Engineering and the War. L. H. Pomeroy. **(29)** Nov. 6.
Armored Automobiles in War.* John J. Ide. **(46)** Nov. 7.
Industrial Uses of Fuel Oil.* F. B. Dunn. **(111)** Nov. 7.
Test of 75-Ton Steel Derrick.* **(14)** Nov. 7.
The Separation of the Illuminants in Mixed Coal and Water Gas.* G. A. Burrell and I. W. Robertson. (Paper read before the Am. Gas Inst.) **(24)** Nov. 9.
Gas Testing Ordinance. Jacques Abady. **(24)** Serial beginning Nov. 9.
Lubrication and Lubricants.* Ray Francis Yates. **(64)** Nov. 10.
A New Rotary Air Compressor.* **(13)** Nov. 12.
Drag-Line Bucket Excavator with Martinson Tractor.* **(11)** Nov. 13.
The Thermal and Mechanical Efficiency of the Gas Engine and Its Influence Upon the Future. A. Vennell Coster. (Paper read before the Rotherham Eng. Soc.) **(47)** Nov. 13.
Welding of High Pressure Mains.* J. D. Shattuck. (Paper read before the Am. Gas Inst.) **(83)** Nov. 16.
Progress in Carbonization Methods in the United States.* (Report to the Am. Gas Inst.) **(66)** Nov. 17.
The First Stumpf Una-Flow Engine Built in America.* **(64)** Nov. 17.
The Cost of Power as a Factor in Locating Industries. H. E. M. Kensit. **(96)** Nov. 19.
By-Product Coke Ovens at Sparrows Point.* **(20)** Nov. 19.
A Large Coaling Station at Toledo; L. S. & M. S. Ry.* **(13)** Nov. 19.
Three-Stage Air Compressor for 2 500-Lb. Pressure. **(13)** Nov. 19.
A Material for High-Grade Castings. J. E. Johnson. (Paper read before the Am. Foundrymen's Assoc.) **(47)** Nov. 20.
Experimental Marine-Type Engine at the South Shields Marine School.* **(11)** Nov. 20.
Internal Corrosion of Colliery Boilers.* Edward Ingham. **(57)** Nov. 20.
An English Stationary Diesel Engine.* **(12)** Nov. 20.
An American Aeroplane with Adjustable Wings.* Carl Dienstbach. **(19)** Nov. 21.
Low Temperature Carbonization Gas Works. G. E. Foxwell. (From *London Journal.*) **(24)** Nov. 23.
Steam as a By-Product of Internal Combustion Engines. J. B. Meriam. (Paper read before the Cleveland Eng. Soc.) **(24)** Nov. 23.
Outdoor Gas Lighting in a Small City. J. B. Jones. (Paper read before the New Jersey State Gas Assoc.) **(24)** Nov. 23.
Design of Ashpits.* T. A. Marsh. **(64)** Nov. 24.
Rolling Mill with Steam Turbine Drive.* **(20)** Nov. 26.
Motor Truck and Trailer Costs.* **(14)** Nov. 28.
Recent Developments in the Manufacture of the Diesel Engine.* H. R. Setz. **(55)** Dec.
Classification and Heating Value of American Coals.* William Kent. **(55)** Dec.
Die Verwendung des Eisenbetons beim Bau von Kohlenaufbereitungsanlagen.* Gotthard Escher. **(51)** Serial beginning Sup. No. 20.
Reinigung von Rauch- und sonstigen Abgasen Niederschlagen von Abdämpfen; ihre Verwertung unter Gewinnung von Nebenprodukten. Gwosdz. **(7)** Sept. 26.
Rissbildungen in gusseisernen Heizkesseln.* Fichtl. **(7)** Oct. 3.
Beitrag zur Entwicklung der Nassbagger.* Schroeder. **(40)** Oct. 3.

Metallurgical.

A New Reagent for Etching Mild Steel.* Walter Rosenhain and J. L. Haughton. **(71)** Vol. 89.
The Colorimetric Estimation of Sulphur in Pig Iron and Steels.* G. Misson. **(71)** Vol. 89.
Experiments on Allotrophy of Iron: Behaviour of Ferro-Magnetic Mixtures; Dilation of Pure Iron.* Carl Benedicks. **(71)** Vol. 89.

*Illustrated.

Metallurgical—(Continued).

The Talbot Process in Comparison with Other Open-Hearth Processes.* Friedrich Schuster. (71) Vol. 89.
The Production of Steel Direct from Ore. Ernest Humbert and Axel Hethey. (71) Vol. 89.
Recent Developments of the Iron and Steel Industry in India.* Aloke Bose. (71) Vol. 89.
The Development of Dry-Cleaning in Blast-Furnace Gas Purification.* Fritz Müller. (71) Vol. 89.
Electrometallurgy. Jos. W. Richards. (2) Oct.
Electric Brass Melting.* G. H. Clamer and Carl Hering. (Abstract of paper read before the Am. Inst. of Metals.) (47) Oct. 30.
The Heat Treatment of Steel.* Harry Brearley. (Paper read before the Manchester Assoc. of Engrs.) (12) Oct. 30.
The Design of the Plymouth Mill.* Gelasio Caetani. (103) Oct. 31.
Quantitative Blowpiping as an Aid to the Prospector.* Siegfried Fischer, Jr. (105) Nov.
Present Status of the Fink Furnace.* H. B. Pulsifer. (105) Nov.
The Hall Process of Desulphurization. H. F. Wierum. (Paper read before the Min. and Metal. Soc. of America.) (105) Nov.
The Gas from Blast Furnaces, Its Cleaning and Utilization.* J. E. Johnson, Jr. (105) Serial beginning Nov.
The Use of Titaniferous Ores in the Blast Furnace. F. E. Bachman. (Abstract of paper read before the Am. Iron and Steel Inst.) (62) Nov. 2.
New Reliance Mill Practice, with Particular Reference to Continuous Decantation.* Jesse Simmons. (103) Nov. 7.
Concentration by the Goltra Process. William B. Phillips. (20) Nov. 12.
Aluminum by Electro-Metallurgic Methods. Juan Blanquier. (Translated by Claude Hafer from *Boletin* de la Sociedad Nacional de Mineria.) (82) Nov. 14.
Spelter Manufacture and Properties. George C. Stone. (Paper read before the Am. Inst. of Metals.) (103) Nov. 14.
Several Methods of Cyaniding in the Black Hills, South Dakota. Jesse Simmons. (82) Nov. 14.
The Turbo-Blower for the Blastfurnace.* F. G. Cutler. (Abstract of paper read before the Am. Iron and Steel Inst.) (47) Nov. 20.
St. Joseph Lead Co.'s Smelting Plant, Herculaneum, Mo.* (16) Nov. 21.
Electric Furnaces for Heating Steel. Alcan Hirsch. (Abstract from *Journal of Industrial and Engineering Chemistry.*) (19) Serial beginning Nov. 28.

Military.

A Modern Military Camp.* (46) Nov. 7.
The Engineer as a Factor in Modern Warfare.* Joseph E. Kuhn. (14) Nov. 14.
Les Principes Actuels de la Défense des Places; La Fortification Cuirassée. A. Dumas. (33) Nov. 1.
Artilleries Lourdes Allemande et Autrichienne, Obusiers de 15, 21, 24, 28 et 42 centimètres.* Ch. Dantin. (33) Nov. 10.

Mining.

The Outlook for Mining in British Columbia. C. E. Cartwright. (5) Vol. 28, Pt. 1.
Initial Proceedings in Opening Up a Coal Mine. C. M. Odell. (5) Vol. 28, Pt. 1.
Dust-Explosions.* John David Morgan. (63) Vol. 196.
The New Coal-Dust Experiments. (From the Sixth Report of the Explosions in Mines Committee.) (22) Oct. 30; (57) Oct. 30.
Power Factor and Its Improvement (for Mines).* L. G. F. Routledge. (Paper read before the Assoc. of Min. Elec. Engrs.) (22) Nov. 6.
The Calumet & Hecla Dredge.* L. E. Ives. (16) Nov. 7.
Cost of Piping Arizona Copper Co.'s New Smeltery.* (16) Nov. 7.
Mining Construction and Equipment News from South America.* (82) Nov. 7.
Recovery of Gold in Dredging.* Charles Janin. (103) Nov. 7.
Dredging in the Russian Empire. (For Mining.)* John Power Hutchins. (16) Nov. 14.
Hydraulic Dredge to Dig to Depth of 100 Feet.* (14) Nov. 21.
A Revolving Annular Drier for Lead Products.* W. R. Macklin. (82) Nov. 21.
Double-Track Steel Ore-Stocking Trestle.* (14) Nov. 21.
Quarrying with Air Hand Drills on Scaffolds, Slings and Ladders.* Charles C. Phelps. (13) Nov. 26.
L'Emploi du Remblayage Hydraulique dans les Couches Puissantes et Moyennes.* (33) Nov. 15.
Ueber die Bewertung eines Moores bei beabsichtiger Brenntorfgewinnung. A. von Vegesack. (52) Serial beginning Sept. 15.

*Illustrated.

Miscellaneous.

Textile Cost Accounting, a Brief Treatise on its Purpose and Application. C. B. Annett and C. F. Cunningham. **(55)** Vol. 35.
Efficiency in Technical Education, a Factor in the Development of Professional Ideals. W. F. M. Goss. **(55)** Vol. 35.
Standard Sizes of Catalogues, Report of Committee on Standardization of Catalogues.* **(55)** Vol. 35.
Patent License Restrictions; the Patent Law as Affected by Recent and Pending Decisions of the Supreme Court of the United States and Proposed Legislation. Edwin J. Prindle. **(55)** Vol. 35.
Errors in Height-Scales of Barometers.* Rollo Appleyard. **(63)** Vol. 196.
Patents on Engineering Structures. Willis Whited. **(98)** Oct.
Present Value of Public Utility Properties. W. G. Vincent, Jr. **(111)** Oct. 31.
The Filing of Engineering Literature, the Dewey Decimal System of Classification to Cover Municipal Engineering. R. De L. French. **(96)** Nov. 12.

Municipal.

Concrete Highway Construction.* Louis S. Brunner. **(5)** Vol. 28, Pt. 1.
Concrete Roads. Alex. A. Young. **(5)** Vol. 28, Pt. 1.
Road Improvement in the Province of Quebec. Gabriel Henry. **(5)** Vol. 28, Pt. 1.
Some Notes on the Development of Wide Roads for Cities.* John Alexander Brodie. (Paper read before the Town Planning Inst.) **(104)** Oct. 30.
Seattle's Central Fire Alarm System.* Howard Joslyn. **(111)** Oct. 31.
Re-Cut Granite Block Paving in Bronx Borough, New York City. George C. Thompson. **(60)** Nov.
Vitrified Brick Street Construction.* Will P. Blair. **(60)** Nov.
Road Building with Convict Labor in Fulton County, Georgia.* W. T. Wilson. **(86)** Nov. 4.
Notes on the Relative Values of Paving Materials. Geo. W. Tillson. (Paper read before the Cleveland Eng. Soc.) **(86)** Nov. 4.
Ashokan Reservoir Roads Built by the New York City Board of Water Supply.* **(13)** Nov. 5.
Concrete Roads in Wayne County, Mich. **(13)** Nov. 5; **(14)** Nov. 7; **(86)** Nov. 11.
Kansas City Specifications for Creosoted Wood-Block Paving.* Clark R. Mandigo. **(13)** Nov. 5.
Rebuilding and Surfacing the Old National Pike with a Concrete Pavement.* **(13)** Nov. 5.
Portable Plant for Asphaltic-Concrete Roads in Chicago.* **(13)** Nov. 5.
How California is Building an $18 000 000 System of State Highways.* Austin B. Fletcher, M. Am. Soc. C. E. **(14)** Nov. 7.
Rolling Concrete Pavement; Base and Surface of Oregon Roads are Compacted by Special Iron Roller Designed by State Highway Engineer.* **(14)** Nov. 7.
Details of Construction Which Make Brick Pavements Good or Bad.* F. A. Churchill. **(14)** Nov. 7.
Rock Asphalt Pavements in Salt Lake City, Utah.* **(86)** Nov. 11.
Adaptability and Cost of Concrete and Macadam Pavement Bases in Oakland, California. **(86)** Nov. 11.
New Municipal Asphalt Plant, San Francisco, Calif.* B. E. Dunn. **(13)** Nov. 12.
Tests of Concrete Road Slabs by New York Highway Department. **(14)** Nov. 14.
Recut Granite-Block Pavements in Baltimore.* **(14)** Nov. 14.
Methods and Cost of Resurfacing Asphalt Pavements in Brooklyn by the Surface Heater Method.* Joseph C. Huseman. (Paper read before the Brooklyn Engrs. Club.) **(86)** Nov. 18.
Cost of Boulevard Lighting and Street Sprinkling and Flushing in Grand Rapids, Mich. (From Annual Report, Board of Public Works.) **(86)** Nov. 18.
Grades and Excavations. A. D. Williams. (Paper read before the Fourth Am. Road Congress.) **(96)** Nov. 19.
An Instrument for Recording Roughness of Pavement Surfaces.* **(13)** Nov. 19.
Methods of Taking Records of Street Traffic. (Abstract of report to the Am. Elec. Ry. Assoc.) **(13)** Nov. 19.
Road Maintenance Costs in France, England and Massachusetts. William D. Sohier. **(13)** Nov. 19.
Street Improvement in Fredericton, N. B.* **(96)** Nov. 19.
The Effect of Leaking Illuminating Gas on Bituminous Pavements. G. C. Warren. (Paper read before the Am. Soc. of Municipal Improvements.) **(24)** Nov. 23; **(60)** Nov.
Organization for and Methods and Cost of State Aid Road Construction in Alabama.* **(86)** Nov. 25.
Notes on Massachusetts Highway Work.* **(13)** Nov. 26.
Relation of Road Maintenance to Traffic. William D. Sohier. (Abstract of paper read before the Am. Road Congress.) **(14)** Nov. 28.
The New York Fire Alarm System.* Putnam A. Bates. **(19)** Nov. 28.
Der Bebauungsplan für das Südgelände in Berlin-Schöneberg.* **(40)** Oct. 3.

GROUTED CUT-OFF FOR THE ESTACADA DAM.

By Harold A. Rands, Assoc. M. Am. Soc. C. E.

To be Presented February 18th, 1914.

Early in 1912, the Portland Railway, Light and Power Company, which is the principal public service corporation of Portland, Ore., completed what is known as the Estacada Hydro-Electric Development. This work, which includes an Ambursen dam, 90 ft. high, with power-house and transmission line, has already been described in several technical journals, and to redescribe these features is not the object of this paper. Inasmuch, however, as the treatment of the foundation material by the grouting process is the greatest thus far attempted, it is believed that a setting forth of this particular feature of the work will prove of interest to many engineers.

The location of the Estacada or River Mill plant, as it is sometimes called, is some 25 miles southeast from Portland, in the extreme western foot-hills of the Cascade Range, at the point where the Clackamas River, issuing from its long and tortuous canyon, begins its course through a rolling alluvial plain. The water-shed above the dam is approximately 800 sq. miles, and though the minimum flow for a short time in the dry months of August and September may fall to 700

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

sec-ft., the average, of course, is much higher, and at times of extreme flood, like that of November, 1909, may rise to 40 000 sec-ft.

Previous Experience.—The Company was not without experience in construction work in these regions. For years it had operated a hydro-electric plant at Oregon City, where the Willamette River drops over a basaltic ledge with a fall of 40 ft. In 1906 it completed the Cazadero Station, 3 miles above the new Estacada plant. The operating head at this station is 130 ft., but the dam, which is 1¾ miles up the river from the plant, raises the water only 45 ft., the remainder being obtained by the flume, ditch, and dike by which the water is conveyed to the forebay. This dam is of logs, and though there is some seepage passing through and around it, this never has been excessive, and Mr. T. W. Sullivan, Hydraulic Engineer for the Company, who completed the work after it had been acquired in an incompleted state from other interests, states that no springs have at any time appeared, either in the bed of the river or in the vertical sides of the gorge, as a result of the dam.

In 1907 the Company began work preliminary to the construction of a dam about 150 ft. high at the head of slack water 2 miles above the Cazadero Dam. Here, under the supervision of S. C. Hulse, Assoc. M. Am. Soc. C. E., extensive borings were put down and tests of various kinds were made to determine the feasibility of erecting so high a structure on the formation found. These borings disclosed rock of so porous a nature that even a moderate pressure applied to the casings of the drill holes produced a leakage of many gallons per minute. Pressure applied to one hole would also cause the water to rise in other holes some distance away. The engineers had the benefit of the knowledge gained by the above construction and experience when in 1909 the Estacada site became the property of the Company.

Preliminary Borings.—At the site proper the river flows through a gorge of lava conglomerate, the sides of which are nearly vertical and from 50 to 70 ft. high. They are capped with a sloping over-burden of gravel, small boulders, and clay from 2 to 20 ft. deep. Preliminary borings, ranging in depth from 60 to 250 ft. and aggregating 2 500 ft. of drilling, were put down on both sides of the river for a distance of several hundred feet up and down stream, as well as on the island which later became a part of the dam.

That the general condition of the Estacada site would be similar to that at the site of the proposed 150-ft. dam previously mentioned was to be anticipated by one having a general knowledge of this region, of its geology, and of the great lava flow which now covers it. Concerning this flow the following is quoted from the Encyclopedia Britannica:

"This is probably the grandest lava-flow known to geology, covering as it does an area of about 200 000 square miles. Commencing in middle California as separate streams, in northern California it becomes a flood, completely mantling the smaller and flowing around the greater inequalities. In northern Oregon and Washington it becomes an absolutely universal flood, beneath which the whole original face of the country, with its hills and dales, mountains and valleys, lies buried several thousand feet. It covers the greater portion of northern California and north-western Nevada, nearly the whole of Oregon, Washington, and Idaho, and runs far into British Columbia on the north. The average thickness is probably not far from 2 000 feet, and the greatest (shown where the Columbia, Des Chutes, Snake, Salmon, and other rivers cut through it) about 4 000 feet. To produce this many successive flows took place, and a very long period of time must have elapsed during which the volcanic actions were going on."

Notwithstanding the universality of this great flood, the formations along those streams flowing westward from the Cascade Range with a rapid descent to the sea, as a rule, present less secure banks than do those traversing the high undulating plateau to the east, as even a casual observer who is familiar with the Snake or Des Chutes River Canyons, with their rim rock and columnar-like structure, may have noted. Concerning this western slope formation Mr. J. S. Diller, of the U. S. Geological Survey, in a report made in 1909 covering the site of the proposed 150-ft., Clackamas River Dam, expressed himself as follows:

"The rocks of this canyon wall are of four forms; volcanic breccia, lava sheets, volcanic dikes and terrace gravels, the volcanic breccia being most abundant.

"The conditions that confront the engineer along the Clackamas river in the volcanic breccia plain region are very much the same as will be found all along the western foot of the Cascade range from the Columbia river in Oregon to the Feather river in California, one of the most important power belts in the United States, and the successful solution of the problem it presents at one point will greatly facilitate the work elsewhere."

To the above, and possibly of greater interest to the engineer, may be added a statement from one, who, from an engineering standpoint, has probably a first-hand knowledge of the entire region second to no one. Certainly, in terseness of language and clearness of expression it leaves nothing to be desired. John F. Stevens, M. Am. Soc. C. E., in a report on the Estacada Dam Site, expressed himself as follows:

"The site of the proposed works lies in the west slope of the Cascade range, and this range is well known to be, geologically taken, as of volcanic origin. Go where we may, for hundreds of miles North or South, we will find the upper valleys, canyons and river beds filled with what we call volcanic débris. Sometimes this volcanic matter appears as the hardest kind of basalt, sometimes as loose and friable as garden soil and generally occurs in every imaginable character and degree of solidity between the two, and it is not probable that nature has made any exception in this particular case. The limited number of test pits and borings which have been made show clearly that as far as the area they cover no well-defined, extremely hard masses of rock exist—that the rock is soft and shades away into clay, the latter appearing under superficial examination much like a half burned brick. The whole formation to the non-geologically scientific man seems to be a mass of soft conglomerate, and this description is borne out in striking manner by the appearance of the nearly vertical walls of the canyon at the site of the dam and immediately adjacent."

Fig. 1, showing the left channel and vertical face of the island in the natural state, gives a good idea of the appearance of the rock. The pitted and scarred surface of the weathered breccia, with its hard irregular fragments embedded in the weakly cemented matrix of indifferent sand, is well shown. In some holes the formation, as shown by the preliminary borings, seemed to be much the same down to the bottom, and in others ledges of hard rock, from 5 to 20 ft. thick, were penetrated; in some the sandy matrix, most common in surface croppings, would change with depth to an even-textured clay, sufficiently compact to give a fair percentage of core; in several holes, though not among those put down on the site finally selected for the dam, this clay at considerable depth deteriorated to such a consistency that for many feet the diamond bit was replaced with a star bit, with which, rotating as did the diamond bit, very rapid progress was made for many consecutive feet.

The sandy matrix and, to a lesser degree, the clay-like matrix were ground away by the attrition of the drills and the harder fragments of

FIG. 1.—LEFT CHANNEL. WEATHERED BRECCIA IN NATURAL STATE.

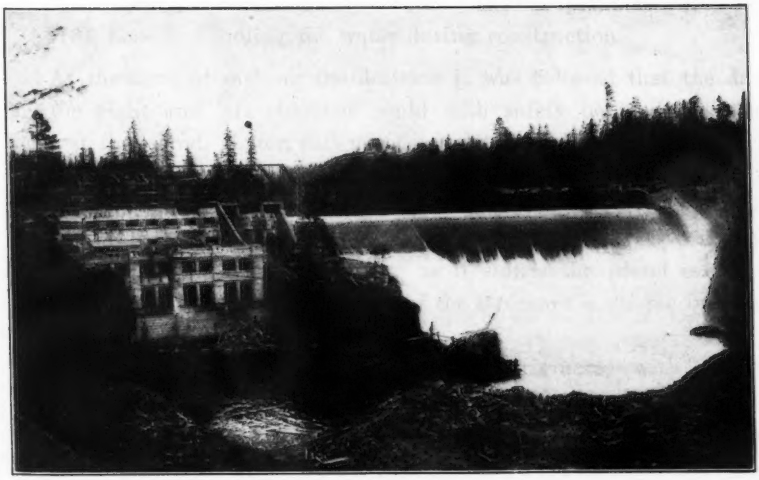

FIG. 2.—DAM, WITH POWER-HOUSE NEARING COMPLETION.

rock so that an average for the diamond bit, using the single-tube core barrel for the Sullivan diamond drill, operated by that Company's expert runners, was slightly less than 50 per cent. The double-tube barrel as used on part of the work gave core amounting to slightly less than 80 per cent. In these borings fragments of wood were passed through at different depths, and in subsequent excavation several stumps, one about 30 in. in diameter, and portions of logs in part petrified and in part in a semi-decayed state were encountered, so that altogether the term "débris" seems most fittingly to describe the material.

The Island Location.—A question constantly being asked by visiting engineers during construction was: Why was the dam located at the island rather than in the narrow gorge some few hundred feet up stream? The reply to this query is as follows:

In the beginning, three sites were under consideration, Site A at the railroad bridge, Site B, 200 ft. below Site A, and Site C, at the island. These are shown on Fig. 3. The reasons which led to the selection of Site C seem to have been:

(1) The soft clay encountered in the preliminary borings already mentioned;

(2) The great length of spillway which was essential, as the crest of the new dam was to be at the same elevation as the low-water tail-race discharge of the Cazadero plant above;

(3) Ease in handling the water during construction.

At the time of making the decision it was believed that the dam in the right and left channels could with safety be made to abut against the island. Later, this was deemed to be taking chances which amounted to gambling with fate, so that over the up-stream side of the island, cut to the slope of the dam, an Ambursen deck, minus most of the steel, was extended. The down-stream slope was also carpeted for a considerable distance, so that as it stands the island is incorporated in the dam, and this portion of the structure is unique in being "a hollow dam" filled with island.

The plan for grouting the foundation originated with Messrs. Sellers and Rippey, of Philadelphia, Consulting Engineers on the work. Their conception of the problem and what they hoped to accomplish is well set forth in a paper by H. V. Schreiber, M. Am. Soc. C. E., and a member of the above firm. This paper was presented

at the Eighth Annual Convention of the National Association of Cement Users. Mr. Schreiber in part said:*

"After a careful study of the conditions disclosed by the investigation it was decided that in order to secure an impermeable foundation it was necessary to practically provide for actually changing the structural character of the underlying formation. To do this Mr. S. Howard Rippey, chief engineer of Messrs. Sellers and Rippey, engineers on the work, recommended that the most promising method would be the solidification of the porous material by the introduction of cement grout under pressure, but that the success of the work must be susceptible of demonstration by actual test before the superstructures should be started. Thorough inquiry failed to disclose any precedent for the use of grout for the general treatment of foundations, although it was found that cavities in limestone rock under the New Croton Dam had been filled with grout, much as a dentist would fill a cavity in a tooth. The grouting method had also been used in filling back of lining walls in tunnels, etc. Notwithstanding the absence of precedent, it was decided to proceed with a grouting scheme and a program was outlined for preventing leakage of water from the reservoir created by the dam, under or around the dam, to the low tail water level below the dam and the experiments which should be made to properly demonstrate the efficacy of the method before the complete development should be undertaken were prescribed. The general idea provided for drilling a double line of holes of an average depth of 50 ft. under the heel of the dam across the entire valley to and under the shore abutments and the subsequent forcing into each of these holes of grout of such consistency as to percolate through the entire substructure.

"It was recognized that experiments would be necessary to determine the proper spacing of the grout holes and their depth, which would insure sufficient diffusion of the grout through the varying material encountered to create a continuous impermeable barrier to prevent seepage of water from the reservoir under the hydrostatic head which would be created by the dam. After drilling the double line of holes, the program contemplated the test of each hole with water pressure, a record being kept of the quantity escaping and the pressure applied to each hole. Upon the completion of the tests, the cement grout was to be pumped into the holes under pressure and after allowing time for hardening, a third line of holes was to be drilled midway between the first two or outer lines and tested with water pressure. The idea was that if water pressure applied to the centre holes at or slightly above the hydrostatic pressure to which the rock would be subjected by the water in the reservoir after completion of the dam and no appreciable leakage occurred, it would be rea-

sonably certain that the cement grout had proven effective in making the entire foundation impermeable."

The drilling for the grouting included 555 holes, aggregating 34 038 lin. ft. For a short time the Sullivan diamond drills, operated by steam, and also the Davis-Calyx shot drills, operated by electric power, were used. The diamond drills, being required at the site of the proposed 150-ft. dam, were released after putting down 1 119 lin. ft., and from that time to the end the shot drills were used exclusively. These drills are made by the Ingersoll-Rand Company, and those used on this work, with one exception, were the small "Class G-O" machine. These may be operated by hand if speed is of secondary consideration, but on this work each was driven by a 5-h.p. direct-current motor which

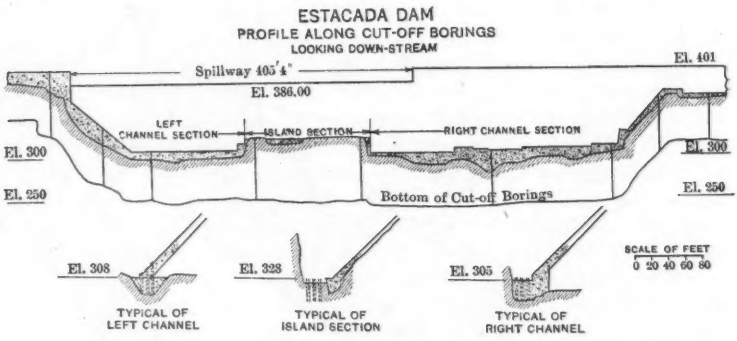

FIG. 4.

gave the bit a speed of 187 rev. per min. The bit had an outside diameter of $2\frac{3}{8}$ in. and gave a $1\frac{1}{2}$-in. core. Seven of these drills were purchased, but only for a short time were all working; the average for the 32 919 ft. put down by them was 13 ft. per 10-hour shift.

Grouting.—The grouting was done with a Canniff air-stirring grouting machine, made by the Tide Water Iron Works, Hoboken, N. J. This wonderfully complete and self-contained machine, in which the air does the mixing and discharging with very little outside work, having been used in the grouting of tunnels and similar work, is now too well known to require description here.* As used on the Estacada Dam, air was supplied at a pressure of 250 lb. per sq. in., and in

* One of these machines was sold later to the U. S. Reclamation Service, and used in grouting the Lahontan Dam of the Truckee-Carson Project. An excellent description of the machine, with drawings, will be found in an article by D. W. Cole, M. Am. Soc. C. E., in *Engineering News*, April 3d, 1913, p. 647.

grouting it was customary to start each hole at a pressure of 25 lb., or whatever was required to start the discharge, and as the hole tightened to increase the pressure, finally ending when at 200 lb. no more grout could be forced in. On this work only neat cement was used. The mixture varied from 1 part cement and 1½ parts water, by volume, to 1 part cement and 15 parts water, the best results seeming to be with 1 part cement and 3, 4, or 5 parts water. In order to prevent the choking of the holes, the scheme was tried of discharging the grout at the bottom of the hole through an inner pipe passing through the cap which sealed the top of the main casing. This method, after a thorough trial, was found of no benefit, and was discontinued.

Arrangement of the Holes.—The plan for the grouting, as proposed by W. L. Fitzgerald, Assoc. M. Am. Soc. C. E., Designing Engineer for the firm of Sellers and Rippey, was that of two lines of holes, 6 ft. apart with 6 ft. between holes in the same line.

These were known as primary holes. To test the effect of the grouting of these primary holes it was proposed that, after allowing a reasonable time for the cement in the primary holes to set, a proving hole should be put down in the center of each square formed by the four primary holes. If this tested tight or reasonably so, that square would be complete. If it did not, additional proving holes would be put down, first on one side and then on the other of the first, so that if all were required in the end there would be four primary and three proving holes in each group.

The Left Channel.

The first grouting done was in the left channel in September, 1910. Across this channel a low coffer-dam, designated on Fig. 3 as Coffer-dam No. 1, had been placed. Back of this a cut-off trench from 8 to 9 ft. deep had been excavated, and through 3-in. casings set with cement 4 ft. in the bottom of this trench, holes were drilled 46 ft. or to a total depth of 50 ft. from the bottom of the cut-off.

The head against the coffer-dam was seldom more than 2 ft., and at times of minimum load at the Cazadero plant, the water receded to the deep-water channel indicated on Fig. 3. Insignificant as this head was, so porous was the ground that it sufficed to cause many of the casings to flow continuously as Artesian wells. Conversely, when pressure was applied to the casings of a number of the holes, leakage

was observed at several points in the river bed, which here was conglomerate bare of gravel, nearly out to the deep-water channel.

Unfortunately, for purposes of comparison, these first holes were tested by a pump taking water from a tank provided with a gauge reading in gallons direct. The pressure gauge was attached to the elbow connecting the water line to the casing of the hole, and the pressures as registered by this and the water taken from the tank were recorded at intervals of 1 min. Tests were made at one-half depth and at full depth for each hole. This method of testing was found to be unsatisfactory, and subsequent tests were made by gravity pressure from an elevated tank also provided with a gauge reading in gallons.

The first attempt to grout was made with the bottom of the cut-off trench bare, but so great was the loss of pressure and the escape of grout through seams in the rock that operations were suspended until the bottom had been protected with a mat of concrete from 2 to 3 ft. thick. At the time of beginning the grouting, though the drills were still working at that point, there had been put down some twenty testing or primary holes. So free was the communication that in grouting one hole it was necessary to cap the neighboring ungrouted holes for some distance in each direction, though it was customary to leave the caps of these holes slightly loose until the air and clear water first forced up gave place to the grout.

Twenty-five holes grouted at this time show results as follows: Average pressure, 19.4 lb.; average leakage, 85.7 gal. per min.; total cement, 167.25 bbl.; average per hole, 6.69 bbl.; most cement in any hole, 40 bbl.

As soon as the grouting was done across the bottom of the left channel, the urgency of getting to work on the power-house and other construction in the right channel made it necessary to blow up the coffer-dam, thus for a time ending operations at this point. This too was unfortunate, for, though it was not known at the time, operations had been commenced in the worst and most porous material encountered on the entire job, and, as future developments were to show, it had to be left but slightly better, apparently, for these efforts.

The Right Channel.

That the construction of the dam proper might proceed with the least possible hindrance from the drills, William H. Cushman, M.

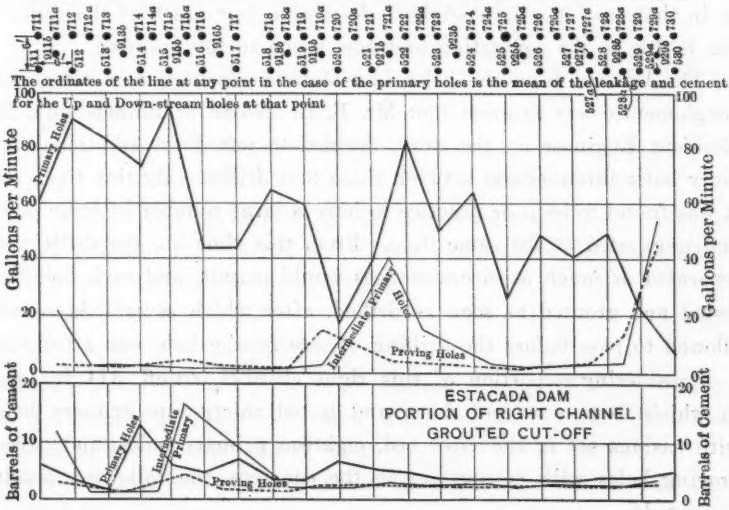

FIG. 5.

Am. Soc. C. E., and representing the consulting engineers, directed that the holes be put down, not through the heel of the dam, as in the left channel, but so as to form a supplementary cut-off immediately up stream therefrom, the plan being to set the casings in the bare conglomerate of the river bottom just back of the cut-off proper, and later, after the grouting and proving were done, to hand-pick a trench to the depth of the casings, namely, 3 ft. or a little deeper. The breccia encountered was sufficiently soft, where speed was not of first consideration, to be removed in this way. This supplementary trench would then be filled with concrete which, bonding with the heel of the dam on one side and with its bottom resting on the curtain-wall supposed to be formed by the grout, would effectually prevent seepage under the dam.

The first grouting was done through casings set in accordance with this plan. However, as in the left channel, the surface material was so lacking in solidity that this method of procedure was not found to be satisfactory, and the plan was modified to the extent of excavating and filling the supplementary cut-off trench before drilling, which was then done through casings set in the concrete. It is apparent that, for purposes of comparison, it is improper to consider the holes tested through casings set in the river bottom with those set in the concrete, as in that case it is impossible to determine how much of the tightening is due to the concreting and how much to the grouting.

The leakage from the holes in which the casings were set in the conglomerate was so great that Mr. F. R. Fisher, of Philadelphia, the Resident Engineer on the work, decided to put down additional primary holes intermediate between those first drilled. By this time, too, it was found to be poor practice to have a large number of holes down and ungrouted at the same time. From this time on, the drills were separated as much as circumstances would permit, and each hole was tested and grouted as soon as drilled, after which several days were allowed to pass before the drilling of any nearby hole was attempted.

Considering a portion of this right channel cut-off, 114 ft. long, in which there were put down and tested thirty-nine primary holes with casings set in the river bed, eighteen primary holes, and twelve proving holes with casings set in the concrete, the following results are noted:

	Gallons per Minute. Maximum.	Minimum.	Average.
39 First primary holes, casings set in river bed....	100	1.0	53.7
18 Second primary holes, casings set in concrete.....	63	1.0	13.0
12 Proving holes, casings set in the concrete.....	44.5	1.2	7.95

The 39 holes first noted, it should be stated, were tested from a tank at Elevation 430, or 46 ft. above the crest of the spillway, and giving a mean head of 182 ft. on the bottom of the hole; the other tests in this, and in the Island and Left Channel Sections following, were made from a tank at Elevation 394, or 7 ft. above the spillway crest, and giving a mean head of 146 ft. on the bottom of the hole.

How much of the tightening, from an average of 54 gal. per min. for the 39 holes drilled and tested before the concrete was placed, to an average of 12.7 gal. per min. for the 18 holes drilled and tested after the concrete was placed, was due to the concrete can never be known. An idea of the relative effect of the concrete and the grout may be deduced by considering an adjoining though somewhat tighter section in which all drilling and testing followed the placing of the concrete. The report for this 54-ft. section is as follows:

	Gallons per Minute. Maximum.	Minimum.	Average.
18 Primary holes, casings set in the concrete.....	17	0.6	4.4
4 Proving holes, casings set in the concrete.....	2.8	0.8	2.2

A comparison of the two tables indicates that but a small percentage of the tightening from 54 to 12.7 gal. per min. in the case of the 114-ft. section was due to the grouting.

Seepage Test.

During construction in the right channel the water above Coffer-dam No. 2 stood at a mean elevation of 317 ft.; behind the coffer-dam, by using pumps, it was held at Elevation 295.

Near the middle of this channel a depression some 30 ft. wide was found in the conglomerate rock. On the cut-off line this was 15 ft.

deep, measured from the average level of the surrounding rock, but on the center line of the dam, 80 ft. down stream, this depth had increased to 35 ft. At some earlier age this depression had been worn smooth by the current, but at the time of building the dam it was

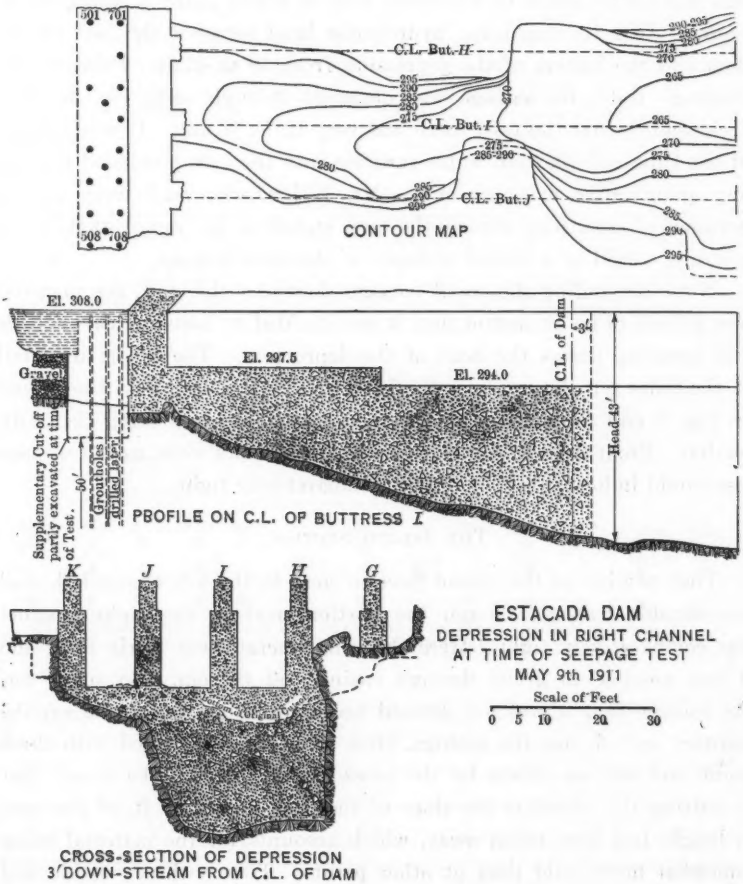

FIG. 7.

filled with loose sand, gravel, and hard boulders. This accumulation was removed, and, as a foundation for the buttresses at this point, mass concrete to a depth of several feet was placed over the entire bottom.

On May 9th, 1911, at which time the concrete had been placed in this gorge to a point 3 ft. below the center line of the dam, and when no drilling and grouting had been done along the cut-off line across the head of the same, the pumps were stopped and the water was allowed to come to Elevation 308, at which point it stood for 6¾ hours. This increased the hydrostatic head between the heel of the dam and the bottom of the depression from 30 to 43 ft. Prior to this "seepage test", no leakage was observed through seams in the bed-rock, and during the test, there was very little, if any. It was raining at the time and the rain water running into the hole precluded making any quantitative measurements. Mr. Fisher, who made very careful personal observations during the test, stated in his report that 2 gal. per min. would be a liberal estimate of the total seepage.

Notwithstanding the small seepage shown by this test, the material was judged to be so erratic that it was decided to continue the drilling and grouting across the head of the depression. The report in detail of the holes put down across the head of this depression will be found on Fig. 6 and summarized in the tabular statement covering the 54-ft. section. From these it will be seen that these holes were, as the seepage test would indicate they should be, comparatively tight.

The Island Section.

That portion of the Island Section next to the left channel showed considerable leakage, though the portion next to the right channel was comparatively tight. Here the conglomerate was fairly firm, and it was possible to grout through casings set therein. So small was the leakage that it was not deemed necessary to hand-pick the supplementary cut-off, but the casings, after grouting, were filled with thick grout and left as shown by the cross-section. It will be noted that in cutting the island to the slope of the deck nearly 50 ft. of the rock in height had been taken away, which accounts for the material being somewhat more solid than at other points. Twenty-three outside and six proving holes put down in this portion show leakage as follows:

Return to the Left Channel.

In the spring of 1911 several proving holes put down in the left channel and tested with the pump, as had been the original holes, notwithstanding the great quantity of cement that had been forced in, showed leakage and intercommunication between holes practically the same as for the holes put down before any grouting was done. When this was discovered, Mr. Fisher decided to put down new primary holes between those drilled the previous fall. These were tested every 10 ft. as drilled. These tests were so remarkable that the result of the work at this point will be discussed in detail.

By referring to the profile it will be seen that at depths varying from 12 to 40 ft. below the concrete, the normal conglomerate gave place to a water-bearing stratum. Through this the drills made good progress, but obtained a very small percentage of core. The washings from the drills, which were saved in great quantities, appeared as a fine sand of the color of brick or garnet. There was little caving, and the holes remained open after being drilled.

Disregarding the holes put down in 1910 and tested with a pump, and confining our attention to the holes put down in 1911, it will be noticed from the record sheet that the primary holes on the down-stream line, with one exception, were grouted before any testing was done on the up-stream line. The up-stream line, then, had the advantage of the grouting of the down-stream line. Consider, further, a group as made up of four of these new primary holes. It will be seen that the proving holes in each group would have the benefit of the grouting of the four primary holes; the second proving hole would have the benefit of the grouting of the four primary holes plus the one proving hole; and the last proving hole would have the benefit of the grouting of the four primary, plus two proving holes. The fact that the first primary holes were staggered, and those put down later were placed opposite, lends some confusion to the grouping, but, in effect,

still disregarding the holes put down in 1910, the drills were passed over the ground five times. This being the case, the holes drilled in each successive passage should show decreased leakage. That this progressive tightening did not follow and that the results were somewhat complicated and disappointing is shown graphically by the curves of Figs. 9 and 10. Tabulated, the averages appear as follows:

	Average Leakage of Holes, in Gallons per Minute, at Depths of:				
	10 ft.	20 ft.	30 ft.	40 ft.	50 ft.
Down-stream primary	10.3	15.0	29.9	33.2	47.3
Up-stream "	3.05	4.3	14.7	47.2	56.9
First proving	1.4	3.9	15.5	50.7	63.6
Second "	1.6	5.1	13.7	22.1	31.7
Final "	2.0	3.8	6.5	15.0	35.6

Cement was forced into these holes as follows:

	Totals.	Averages.
14 Down-stream primary	117.75 bbl.	8.38 bbl.
13 Up-stream "	79.25 "	6.09 "
11 First proving	21.50 "	1.95 "
12 Second "	20.25 "	1.84 "
17 Final "	26.50 "	1.55 "
67 Holes in all	264.75 "	3.95 "

If to the above are added the 28 holes put down in 1910, taking 172.5 bbl. of cement, and the 7 proving holes put down in the spring of 1911, tested with pump, and not in the above, taking 17.75 bbl. of cement, we have for this 84-ft. stretch of cut-off a total of 102 holes, aggregating 5 050 ft. of drilling, and into which was forced 455 bbl. of cement.

The average leakage of the final proving holes at each different depth, as shown by the foregoing table, expressed as percentages of the average leakage of the down-stream primary holes at the same depth appears as follows: At 10 ft., 20%; at 20 ft., 25.3%; at 30 ft., 21.7%; at 40 ft., 45.1%; at 50 ft., 75.2 per cent.

Back-Flow.

More strange, possibly, than the persistence with which the leakage continued, in spite of all the cement forced in, was the fact that with nearly all these holes, as with those put down in 1910, a very

insignificant head produced a back-flow from the river. At this time the construction of the dam had completely blocked the right channel, so that operations were carried on in the left, behind coffer-dams which blocked off first one and then the other half of this channel, and from these resulted the head which produced the flow.

The average depth at which the back-flow commenced in the case of the down-stream primary holes was 27.2 ft.; the up-stream primary, 32.0 ft.; the first proving, 27.7 ft.; the second proving, 32.5 ft., and the final proving, 35.0 ft.

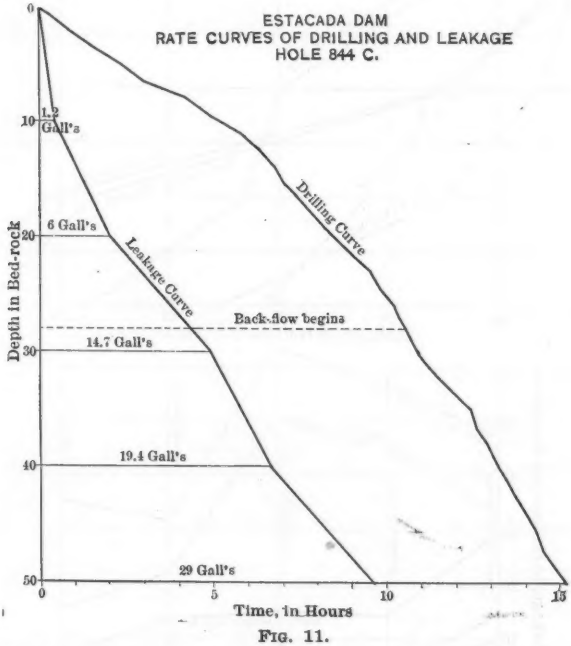

FIG. 11.

The depth below the bottom of the concrete cut-off at which this flow commenced, the head producing it, and the gallons per minute for 14 of the final proving holes, are given in Table 1.

In Table 1, under head, is given the vertical distance that the top of the casing is below the level of the water against the coffer-dam. This small head, averaging only 4.4 ft. for these 14 holes, produced a back-flow averaging 12.7 gal. per min., or one-third of the average leakage for the same holes when tested from a tank some 70 ft. above

the level of the water against the coffer-dam. In one hole, 845*a*, the back-flow, under a head of 7.7 ft., was 30 gal. per min., though the same hole, under test, leaked only 35.5 gal. per min.

TABLE 1.

846*a*′	42	6.7	4.0
Average.....	33	4.4	12.7

Not only did the leakage continue and the back-flow persist, but the communication between holes was present even to the 17 final proving holes. In fact, by a system of piping, 13 of these final holes were connected and tested at one time. This, as well as other combination or multiple tests at other points of the cut-off, showed much less average leakage per hole than the average of the same holes tested singly. However, the fact that 17 holes put down along a stretch of cut-off 84 ft. long, in which 84 holes before them had taken 427.5 bbl. of cement, could communicate so freely that pressure from a tank on the crest of the dam applied to any of them would cause water to flow from the other 16 was poorly offset by the fact that 13 of these same holes when tested in combination showed an average leakage of 17.5 gal. per min. as against an average of 34.4 gal. when tested individually. This reduced leakage in the cases of the combination tests was interpreted as indicating that several holes intercepted the same seam or seams.

Grout in the Cores.

At one point, where a trench was excavated subsequent to the grouting, the cement could be traced as a white thread completely filling a seam ½ in. wide for 38 ft. This, of course, was only a few

feet beneath the surface. At greater depths the only evidence of the diffusion, aside from the decreased leakage in testing, would be the cement brought up as core or in the cement flakes in the wash from the drills. The grayish color of the wash, indicating that the drill was penetrating grout, was of much more frequent occurrence than the finding of solid grout in the cores. Of course, where the drilling of the proving holes followed in a few days or weeks the drilling of the primary holes, it was to be anticipated that the cement would be ground up by the attrition of the bits, the shot, and the harder particles of rock. After a lapse of several months, cement core might be obtained, but even then it would be best to use a double-tube core barrel. However, all cores were carefully inspected for any traces of cement, and, though some *bona fide* samples were found, they were very rare.

The words *"bona fide"* are used advisedly. At one time, owing to the poor showing being made by the grouting, there was serious thought of discontinuing it altogether. At this juncture, as the writer discovered later, at least one driller, moved by a commendable desire to see his job continue, joined short pieces of core with cement, which sample, deposited in the core box, was later seized on and carried up to the office as conclusive evidence of the diffusion of the grout.

Tests After Completion of Dam.

For a period of nearly 2 weeks after the pond had been allowed to fill, to admit of completing the excavation of the tail-race, the sluice-gates would be opened at night and closed during the day until such time as the water was nearing the crest. This, save for pools and pot-holes, left the left channel dry for several hours each day, and during these intervals careful daily inspections were made to detect any springs resulting from the 80 to 90-ft. depth of water above the dam. None was found, and the only seepage of any kind was very small in quantity, coming from well up on the left slope. The dam was completed at the time the fall rains set in, and this very insignificant seepage was believed to be due to the filling of the swales and depressions which occurred at intervals in the nearly level bench topping the left bank at the site of the dam.

When the water was flowing over the crest, a core drill was taken inside the dam and two holes put down. The first of these was next

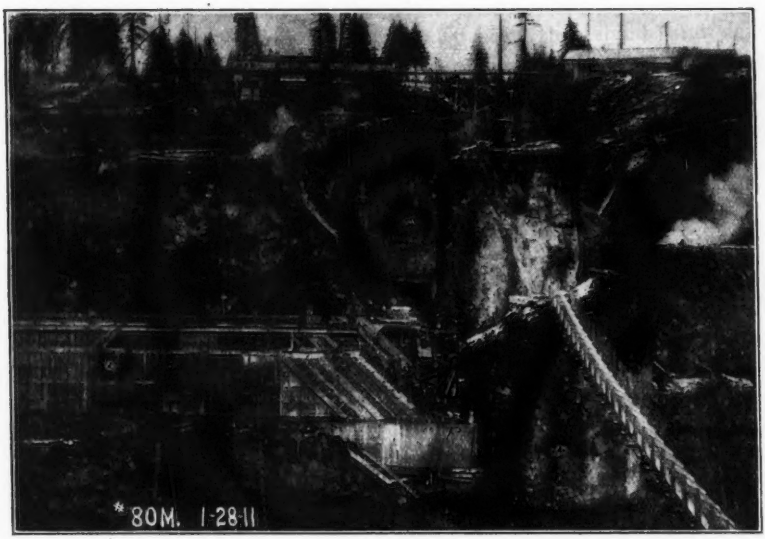

FIG. 12.—VIEW FROM LEFT BANK. ISLAND BEING CUT TO SLOPE OF DAM.

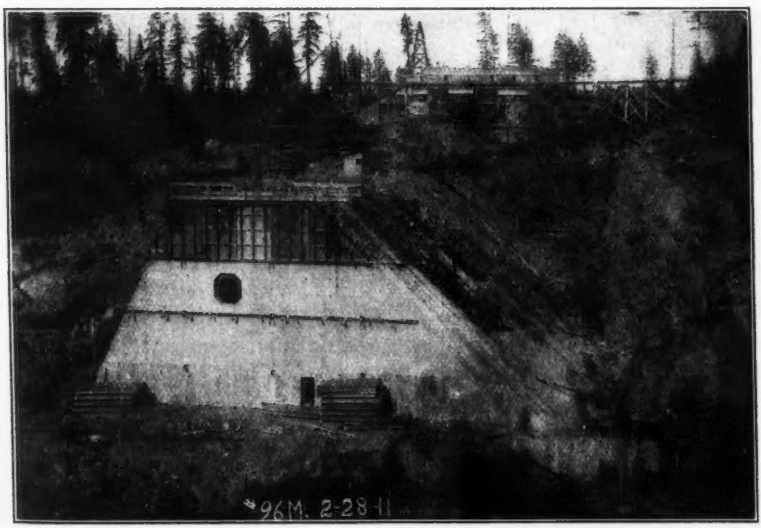

FIG. 13.—VIEW FROM LEFT BANK. DECK BEING EXTENDED TO INCORPORATE ISLAND IN DAM.

the left channel on what had originally been the island, and at a point 35 ft. down stream from the lower side of the grouted cut-off. Table 2, which is an abridgment of one appearing in Mr. Fisher's report to the owners of the plant, shows that water commenced to flow when the drill had penetrated the rock to a depth of 28.5 ft.

TABLE 2.—HOLE No. 1 000.

Elevation, top of casing.....328.2
" of bottom of rock at hole.....325.0
" bottom of concrete cut-off opposite hole..306
" grouted cut-off opposite hole.....248

Elevation, bottom of hole.	Elevation, water in pond.	Flow over top of casing, in gallons per minute.
296.5	375	First trace of flow.

280.5	387	2.2
270.5	387	5.4
260.5	387	5.4
249.0	387	6.6
245.5	387	7.5

The head, or difference of level, between the top of the casing and the water in the pond, with the exception of the first two determinations, is constant, and amounts to 59 ft.

A few days later, when the water in the pond stood at Elevation 388.4, the casing was extended upward with 1¼-in. pipe, great care being taken to have all joints tight. When the water finally came to rest it was found to be at Elevation 364.2 or 24.2 ft. lower than the water passing over the crest above.

The other hole was put down directly in the left channel, and opposite that point in which the leakage had been most serious and the rock most refractive to tightening by the grouting process. This hole, No. 1 001, was opposite Hole No. 644*a* and 30 ft. down stream from the lower line of the cut-off. The first trace of flow from this hole was at a depth of 22.9 ft. in the rock.

In this hole the casing was extended and the height to which the water would rise was determined at intervals as the drilling progressed.

In this case the difference between the top of the casing, the point at which the flow was measured, and the elevation of the pond was nearly constant, and amounted to 79.5 ft.

TABLE 3.—HOLE No. 1 001.

Elevation top of casing.....315.1
" of rock at hole.....308
" bottom of concrete cut-off opposite.....302
" " " grouted " " 248

Elevation, bottom of hole.	Elevation, water in pond.	Flow, in gallons per minute.	Elevation at which water came to rest.
285.1	.....	First trace of flow.	315.1
283.1	387.5	0.7	368.0
281.6	387.1	16.9	369.4

Total cost	$68 266.54	$2.00 per lin. ft.

CONCLUSIONS.

In a piece of work of this character and magnitude, where much is experimental, nothing would be gained in attempting to present a

FIG. 14.—GENERAL VIEW, LOOKING DOWN STREAM. ISLAND CUT TO SLOPE OF DAM.

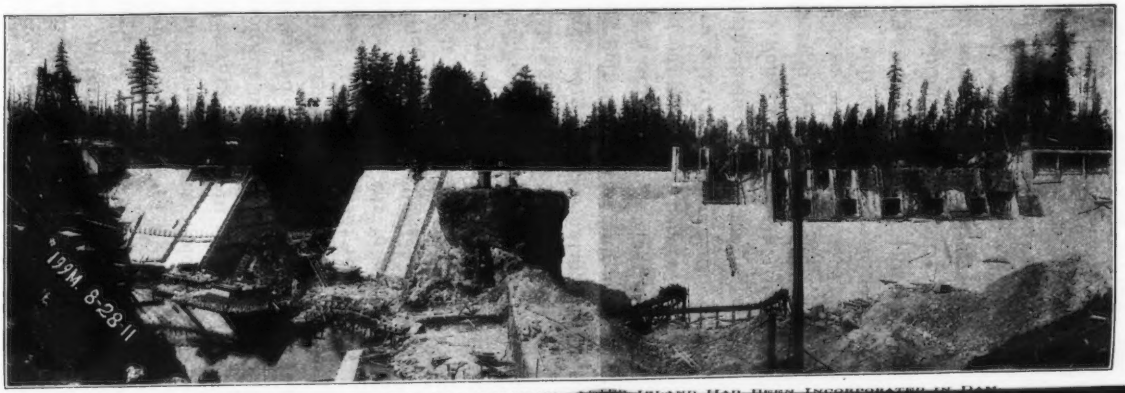

FIG. 15.—GENERAL VIEW, LOOKING DOWN STREAM. [illegible] HAS BEEN INCORPORATED IN DAM.

review or an epitome of the work as a whole, such, for example, as giving the average leakage of all the primary holes and contrasting this with the average for all the proving holes. Such a marshaling would impart, not information, but misinformation. One of the reasons for this is that any hole put down near one already grouted is in a sense a proving hole, whether in the middle or in an outside line of holes. Other reasons are: that the testing was done in part by pump and in part by gravity; in part from a tank at one elevation and in part from a tank at a different elevation; in part through casings set in the conglomerate before the cut-off trench was concreted and in part through casings set in the concrete with which the trench was filled. For these reasons, it seems best to rest the case with the consideration of the several portions of the work taken up in the preceding pages. These cover portions of the cut-off where the material was best as well as where it was poorest; where the grouting was most effective as well as where its benefits were least marked.

Several engineers from different parts of the country, who visited the work during the closing days of construction, attached considerable importance to the great flow from the two holes put down inside the dam, and to the fact that the pressure encountered was sufficient to raise the water to within a few feet of the crest of the dam. The opinion seemed to be that the pressure and flow proved the failure of the grouting process. To the writer, they mean merely that the water passing through the grouted cut-off at a depth of 25 to 30 ft. is stopped or greatly checked in its flow by the denseness of the rock in front, and is held down by the denseness of the rock above. The pressure and flow, in view of this, seem to indicate, rather, that the grouting was not needed, though this is assuming that the tightness of the surface rock is in no degree due to the grouting.

The writer is of the opinion that most engineers who have followed this description will have concluded, in so far as this job is concerned, that over a portion of the cut-off no grouting was needed, and that over those parts where it was needed it did little good. The initial tightness over a part of the right channel and island sections, as shown by the seepage test and pressure tests, and the great leakage, communication, and back-flow of the final holes in the left channel afford ample basis for such an opinion. However, calculating for a head of 80 ft. and assuming an efficiency of 50% for power delivered to

the customer, it is found that, at $33 per kw-year, a saving of 26 sec-ft. would pay 7% on the $41 000 representing the direct cost of the grouting. Whether or not this quantity of water has been saved, no one can say. Even had the first primary holes shown very free leakage and the final proving holes tested absolutely tight, it would not have been known, so different are the conditions when water is forced through a casing into a hole 50 ft. in the rock from those when the pond is filled and there is no such penetration to the interior rock.

In rock having continuous seams, the grouting process would probably be much more effective than in the "volcanic débris" of the Clackamas Canyon. In this, though the grout will fill the larger cavities and interstices, it cannot be called a success, in so far as its being an agent for providing means for actually changing the structural character of the formation, as was hoped when beginning the work.

The knowledge gained by the experience at Estacada may be summed up as follows:

(1) Do all drilling, testing, and grouting through casings set in the concrete cut-off.

(2) Do all testing from elevated tanks, and not by pump.

(3) Test and grout each hole as soon as drilled, and for a few days thereafter keep the drills away from the probable zone of diffusion.

(4) In grouting, especially at high pressures, it is best to close the valve before the tank is entirely empty, as the air following the grout into the hole is apt to make trouble.

(5) Begin with a comparatively thin grouting mixture and, if taken freely, thicken until each succeeding batch requires either an increased time for discharging or an increased pressure. To force charge after charge of thin grout into a hole probably means in a great measure the wasting of cement.

The writer's opinion, now, is that either a single row of holes with close spacing or two rows of holes very close together in an up-and-down-stream direction, with casings staggered, is preferable to the triple line used at Estacada. At the Lahontan Dam, of the Truckee-Carson Project,* two rows of casings were put down, the distance be-

Engineering Record, March 29th, 1913, p. 340; and *Engineering News*, April 3d, 1913, p. 647.

tween the rows was only 2 ft., and the distance between the holes of each row, 3 ft. As the casings in the two rows were staggered, it virtually amounted to a casing every 18 in. Over one section of this work, every fourth hole in the up-stream line of casings was first drilled, tested, and grouted. When the end of the cut-off was reached, the drills were returned to the beginning and the middle hole in each space was drilled, tested, and grouted, after which the drills were returned a third and a fourth time, drilling the remaining holes. This made every hole after the first, a proving hole, and as practical tightness was secured with the drilling of the up-stream line, the casings of the down-stream line were not needed, and were drilled through in only four or five instances as final proving holes.

The experience at Estacada indicates that the grouting should in no case be relied on in lieu of the usual concrete cut-off. There are two reasons for this:

(1) The efficiency of grout as a curtain-wall cannot be foretold.
(2) The proper diffusion of the grout can be secured only when the concrete of the cut-off closes the surface seams and confines the pressure to a depth at which it may be effective in tightening the underlying material.

Where very porous material is encountered below the practicable limit of depth for a concrete cut-off which, as in the case of the left channel at Estacada, proves refractive to the tightening by the grouting of isolated holes, the desired end might be secured by drilling a great number of holes close together and by springing the rock with small charges of powder from the bottom up to the top of the water-bearing stratum, thus shattering and loosening up the intervening material so that the grout would then form an impervious barrier.

As already stated, the pressure testing, though affording one means of measuring the effect of the grout, by no means proves it to be necessary.

In the case of a storage dam, the best plan would seem to be to set the casings in an offset cut-off just up-stream from the heel of the dam, as was done along part of the dam at Estacada. Through these casings a hole could be put down every 12 to 16 ft. to make sure that there were no large crevices. These casings should be tested and grouted and the need for further drilling and grouting left to be determined

by the filling of the pond. If the leakage were excessive and the seams did not tighten by the natural silting processes, the pond, at time of minimum storage, could be entirely emptied and the grouting continued. In this case it would be necessary to grout only at those points where seepage showed it to be needed, and, if tightness were secured, the engineer would have absolute proof of the efficiency of the process. Of course, with an earth dam like that at Lahontan, already mentioned, this method is impossible, and grouting must precede the construction of the dam proper.

In the case of a power dam, the same plan might be followed, and drilling and grouting done by drawing off the water at the time of minimum flow. Whether to do this or to carry the grouting along with the building of the dam, as was done at Estacada, is a problem the solution of which depends on what the minimum flow power is worth and whether the load might, without any great inconvenience, be transferred to other plants for a short time.

The consulting engineers on this work were Messrs. Sellers and Rippey, of Philadelphia. They were represented at various times and in various capacities on this and other projects of the Company, including the proposed 150-ft. dam on the Clackamas River, by Messrs. William H. Cushman and H. V. Schreiber, Members, Am. Soc. C. E., and Messrs. W. L. Fitzgerald and S. C. Hulse, Associate Members, Am. Soc. C. E.

A. Gardner, Assoc. M. Am. Soc. C. E., represented the Ambursen Hydraulic Construction Company, of Boston, owners of the hollow-dam patents under which the dam was built, and L. I. Fletcher, Assoc. Am. Soc. C. E., was Superintendent for the contractors, the Puget Sound Bridge and Dredging Company.

Mr. T. W. Sullivan is Chief Hydraulic Engineer of the Portland Railway, Light and Power Company, owners of the plant, and Mr. F. R. Fisher was the Resident Engineer on the dam. The writer was Assistant Engineer of the same Company, and was connected with the work from the time of making the survey to the delivery of power.

THE DIVERSION OF IRRIGATING WATER FROM ARIZONA STREAMS.

By A. L. Harris, Assoc. M. Am. Soc. C. E.

To be Presented February 18th, 1914.

Most of the irrigating water obtained from Arizona streams comes from the higher mountains. Very little rain falls in the lower and more level country, where cultivation is practicable. For ages the typical stream has gathered its load of silt, sand, and gravel in these mountains and forced it, by reason of strong slopes, through the canyons and down to the low country, where grades become less, and it is spread out evenly in the broad, gently sloping, cultivable valleys. Usually, such valleys show evidences of having been flowed by slack-water for periods long enough to deposit deep surface beds of fine silt. The overflow has eventually cut its way out through surrounding hills, and worn down the outlet below the valley level. A channel has then been cut across the valley floor in the alluvium, toward which channel the surface slopes and drains on each side. The irrigated valley is now like a great shallow dish, inclined a little, and with the bed of the stream running across it in the direction of its slope. By intercepting the river water with a dam where it enters the valley from the surrounding hills, it may often be diverted into two canals, one to the right and one to the left of the stream. Throughout a wide

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

circuit around the edges of the dished valley the canals are located, with gentle grades to insure the flow and with the water surface generally a few inches above the natural ground to enable the water to be taken out at intervals. Of course, it is then possible to draw water into ditches from one of these canals to irrigate any piece of land between it and the river, as there is always a slope in that direction. As the river seldom flows through the middle of the valley, the area of irrigable land under each main canal is not the same. Indeed, it often happens that practically all the irrigable land of a valley lies on one side of the river. The great Salt River Valley about Phœnix has about twice as much irrigable land on its north side as is found on the south, and the Agua Fria and Buckeye Districts, on the Agua Fria and Gila Rivers, respectively, each utilize practically only one side of the stream.

Were it not that the arid nature of the country still allows erosion phenomena to go on vigorously, the provision of works for diverting the irrigating water would be much simpler. For some years the writer has frequently been called on to design diversion works in connection with both United States Government and private irrigation projects in this region, and this paper deals with the principal features and conditions relative to this experience.

Conditions to be Met.

The natural conditions in the locality of diversion present a stream having a flow which varies between very wide limits, and subject to very sudden changes. The floods often carry large quantities of water in great rushes, bearing down with them all kinds of drift—on the surface, in suspension, and grinding along the bottom—wood, silt, sand, gravel, and boulders. The works will be subject to much heat and dryness, but no ice (except on the plateaus of northern Arizona). The range of surface temperature is 160° or more. It is difficult to find an all rock foundation, as the river bed generally consists of a deep canyon, with rocky sides, which has been nearly filled with drift.

For the requirements of irrigation, diversion works must be such that the flow of water shall not be interrupted during long periods in the growing season, which, by the way, in southern Arizona, is nearly 12 months in the year. Canals should be kept free from sand and gravel, but the fine silt carried in suspension is valued highly by the

farmer, for keeping up the strength of the soil, very little other fertilization being necessary. If the system includes a storage reservoir somewhere up stream, much of this valuable silt, unfortunately, is deposited in the bottom of the reservoir, where, for the most part, it is not only useless but in time becomes a serious problem. The capacity to divert and distribute promptly unusually large quantities of water in flood times is generally required. Surface drift must be kept out of the canals. The layout of the whole works must also be such that the banks of the canals, where near the river, will be protected from the washing of the waste waters when floods pass down the river.

The Diverting Dam.

For diverting water into the canals, some kind of dam is generally required, although in special cases a subterranean collector conduit is used. It is generally necessary to raise the elevation of the water considerably in order to place the canals above the reach of flood water and to raise the surface level in them as much as possible for serving the greatest area of irrigable land.

The original diverting dam for irrigation was merely an obstruction of brush, stone, and earth projecting into the stream (as a wing) or across it, and deflecting the water into a ditch at about the natural level of the stream bed. Any small rise in the river destroyed it, and it had to be rebuilt. The point where the river water entered the canal was generally chosen at a place naturally suited to withstand the wear of flood, as by cutting through a projecting rock ledge or boulder point. The most serious expense and loss with such a canal head was not that of rebuilding the brush and stone dam, but the loss of crops due to the interruption of irrigation. However, by the hard and persistent work of the pioneers, most of the irrigated districts in Arizona were started and developed from such a beginning.

The next step in improvement was by the use of timber and rock-filled crib dams. Although a dam of this type can doubtless be made to perform the required service, its common history in Arizona has been that, because of insufficient protection of the foundations, or by ill chosen dimensions governing discharge, it has been sooner or later breached by a flood, causing heavy losses. In the absence of accurate flood data, and even when such data are at hand, it is difficult for the designer to appreciate the destructive action to be provided against

in damming these streams, except after first-hand experience. Usually, the river presents a very shrunken appearance, because of dry weather, and the intervals between extreme floods, often extending through a considerable number of years, give time to cover up and age the evidences of their action.

In this climate, timber is an even more temporary material than usual. All its possibilities for warping and checking are brought out by wetting followed by much heat and dryness. The necessary iron fastenings are hastened in rusting by alkalies often contained in the water. As this timber must usually come from Oregon and Washington, by way of Southern California, it is also expensive. At the present and prospective prices of cement, the expense of timber-crib dams in this locality is not justified by their enduring qualities.

Some diversion dams have been built of cemented stone masonry, but of late the most suitable and available material has proved to be concrete. Concrete materials are found at or near almost any diversion site. The excavated materials from the foundation trenches often prove to be quite suitable. Thus it appears that, for most cases in this locality, a concrete dam and intake works suitably designed and constructed is, both economically and structurally, about the ideal structure for diverting irrigating water. The concrete dam is usually carried entirely across the stream, but, on account of expense and poor foundation conditions, it sometimes appears advisable to build, next to the intake gates, a wing-dam of permanent construction, which acts as a spillway for moderate floods; and to maintain a dike of earth with a higher crest to a closure on the opposite river bank. This dike is expected to go out in the heavier floods, and then must be replaced.

The main features of the complete diverting dam, which is practically always of the overflow type, are the foundation, the apron, the rollway, the sand sluices, and the canal intakes.

Where bed-rock cannot be secured for foundations, excavation will generally discover beds of heavy boulders deposited by the stream, tightly packed together and chinked in with gravel and sand. On account of the usual position of the diverting dam at the mouth of a canyon, as mentioned previously, the heavier products of erosion coming from the mountains can be confidently looked for in the bed of the river. The deposits grow progressively coarser as the depth increases. A series of rather heavy walls is laid out and built in

trenches excavated down to the best gravel or boulder bed within reach. The dam is supported mostly on these walls, but is assisted by the undisturbed masses of gravel lying between them. The arrangement of walls consists of a deep one, put in by timbering and pumping, running lengthwise of the dam under the heel, and a somewhat shallower one under the toe. These two main walls are connected by cross-walls at intervals of from 20 to 40 ft. The heel-wall should be tight; the toe-wall is pierced by ample weep-holes to relieve underpressure. The driving of sheet-piling is often impracticable on account of boulders. The foundation walls are brought up to the level selected for the bottom of the main section, and the material in the spaces between them is leveled to correspond. The solid gravity section is then laid on the whole as a foundation. By thus placing the bearing surface of the foundations deep, the danger of undercutting is minimized.

The principles of analysis used by the writer in determining a practical cross-section, for two of these dams which have been built and well tested, are simple, and can be seen by reference to Fig. 1, which was the writer's study in planning the Granite Reef Dam. The space behind the dam may always be expected to fill to the crest with river deposits, hence the provision for mud pressure. Although the cross-section is chosen for stability against overturning, using the bottom of the main section as a base, the foundation walls are monolithic with the upper parts, and contribute a heavy additional weight and frictional resistance acting against such overturning forces. As to sliding: the gridiron foundation walls enclose a very heavy mass of gravel which must be moved along with the structure or be separated from it by the parting of the concrete walls, either contingency being very strongly resisted. The underflow through the deposits beneath the dam has been found in excavations to be slow, and on account of the quantity of coarse material not easily washed, the first flood with its silt deposit makes an efficient stopper of seepage.

The upward pressure beneath the dam to be chosen for these cases is uncertain. The design of the Granite Reef Dam was made before the publication of the interesting analysis of upward pressures by G. E. P. Smith, Assoc. M. Am. Soc. C. E., and Professor H. C. Wolff, of the University of Wisconsin, contained in discussions on "Dams on Sand Foundations," by Arnold C. Koenig, Assoc. M. Am.

FIG. 2.

Soc. C. E.* Applying the test of that analysis, however, to Fig. 1, shows that the upward pressure was taken at more than enough to satisfy the requirements. By Mr. Smith's curves, on page 199 of that analysis, the average upward pressure on the whole bottom width of the dam, calculating H from the top of the apron instead of at the river bed, would be about 0.33 of the pressure due to a head of water of 20 ft. This would give a total of 18 000 lb. per running foot of dam on the bottom of the main section, as compared with 21 940 lb. used in the writer's old study; this, too, when applying the average pressure to the full width of bottom without excluding the 12 ft. taken up in the thickness of the foundation walls. Pressures on the bottoms of these foundation walls may be assumed to be greater per square foot than those on the base of the dam where they join it, but will not equal the weight of the walls themselves. All these upward pressures are lessened after the silting up has occurred above the dam.

The writer does not forget that the analysis, the test of which he applies here, assigns the maximum under-pressure at low water. He is also aware that the resultant of the upward pressure of Mr. Smith's diagram will not come in the middle of the base, as taken by the writer. However, the difference of head between the heel of the dam and the toe of the apron, for the case of flood assumed herein, will be about equal to the head at low water. The writer also finds that an upward pressure of 18 000 lb. applied to one-third of the base from the heel of the dam—as if the pressure diagram were a triangle—will still keep the total resultant force inside the middle third.

By the openings in the toe curtain-wall for relieving pressure, together with the method of jointing the apron, it is believed that the point of least upward pressure for the dam is at or near the toe of the main section, instead of farther under the apron. As will be seen later, though the pressure is relieved over the width of the apron, there is small chance for the surface or underground water to carry away material to cause undermining.

During a flood, as shown by Fig. 3, the water glides over the ogee and across the apron at a high velocity, and stands in a great wave just about at the down-stream end of the apron, where it strikes the gravel of the river bottom. The general level of the tail-water is several feet higher than that over the apron. At these times, so far

FIG. 3.—SALT RIVER PROJECT: GRANITE REEF DIVERSION DAM IN FLOOD.

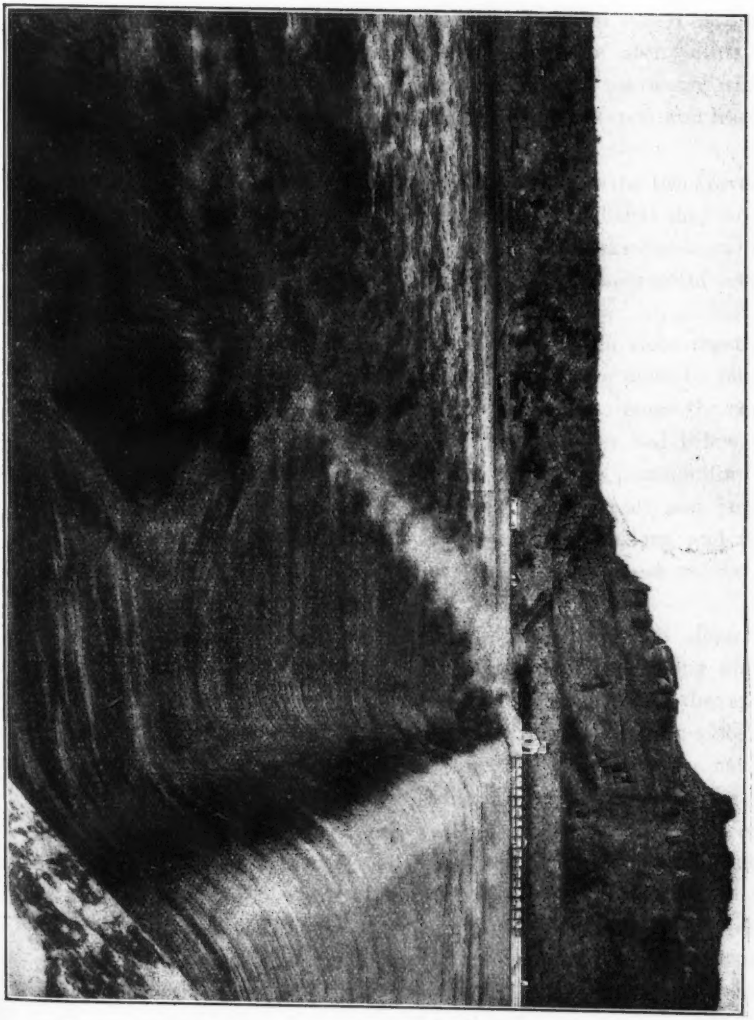

FIG. 3.—SALT RIVER PROJECT: GRANITE REEF DIVERSION DAM IN FLOOD.

as the hydrostatic pressures under the structure are concerned, the apron with its open joints must be an area where under-pressures from above the dam and from the tail-water below are both relieved. It can be readily seen that with a tight apron of small thickness, dangerous upward pressures might be brought to bear on it. It is quite conceivable that the swiftly passing water over the open joints of the apron exerts some suction or injector action on the water which rises from beneath, thus assisting the escape of those waters and lessening their pressures.

No expansion or settlement joints were provided in the two Government dams referred to, and no evidences have appeared that they would be desirable. The dams have developed a few transverse cracks, which are no detriment, as they will silt up. There is also no sign of settlement shown by the cracks.

It is well to keep the dam and the various gates close together, usually in one continuous structure. The sand sluices must be placed with the object of disposing of sand which threatens to enter the canal intake. This sand can best be deposited in the river bed below the dam, to which place it is usually sluiced through a passage for the purpose. A good arrangement is to combine the gates and intake structures with the abutment wall at the end of the dam, and it is very desirable for this purpose to have bed-rock at these points for foundations.

Very careful attention must be paid to the apron laid along the bottom of the stream to protect the toe of the dam from being undermined. Even where a bed-rock foundation is practicable, the apron has been found to be a part of the structure very vital to its stability. Its surface should be placed at a level from 2 to 4 ft. below the natural bed of the stream. A gravel bar will then form just beyond its downstream edge which will back the water over the apron and keep a water cushion always at the toe of the dam for receiving the shock of the overflow. The width of apron sufficient to protect the toe of the dam varies according to the height and volume of the overflow and the consequent scouring energy of the water. The depth of high water above the crest will also influence the width. The apron is of concrete, but must not be connected to the dam, or in one continuous sheet. Being laid on beds of gravel and boulders near the surface, it will heave and settle more or less, and, if laid in a continuous sheet,

this action cracks it into irregular, sharp-angled slabs which are likely to be shifted and undermined by the flowing water.

A satisfactory apron was made for the Granite Reef Diversion Dam by preparing a bed of packed clean boulders in which many of the stones projected prominently. A bed of concrete, about 18 in. thick and divided into 10-ft. square slabs by vertical joints, was laid on top of this foundation. On account of the adhering boulders on the under sides of the slabs, together with their weight, they are adapted to offer great resistance to sliding. The dam raises the water level 20 ft. The apron was 75 ft. wide, down stream from the toe to the dam. Besides dividing the apron into heavy slabs of definite shape, the joints between the slabs also served to relieve the upward pressure of underflowing water during the first few months, while the river bed above was sealing itself up with silt and sand. A curtain-wall, braced with piles and waling pieces, was used to strengthen the unsupported edge of the apron. A similar apron has proved satisfactory at the Diversion Dam of the Government Power Canal on Salt River, 19 miles above the Roosevelt Storage Dam.

The rollway has a surface sufficiently outside the path of free fall to be sure that an adhering nappe is preserved. The writer does not favor a turned-up toe for the main section, as it tends to cause increased agitation of the water on the main structure. It is better to let this energy be spent on the apron and on the bar below it. This result was secured at Granite Reef, as illustrated by Fig. 3.

Gates.

The entrance of sand into the canals has been resisted by using the principle of skimming the less turbid water from near the surface. A forebay is walled off on two sides, in the form of a comparatively deep channel running directly in front of the row of intake gates; it is open at the upper end and given outlet at the lower end by large sluice-gates emptying through an opening in the dam. The intake gates draw water from this forebay at a level considerably above its bottom, and the sluice-gates, which have large capacity, draw from the very bottom of the forebay, which has a good slope toward them. In entering the forebay, the motion of the water is checked by the increased cross-section, and the heavier sand grains settle to the bottom. At intervals the sluice-gates are opened suddenly by a hydraulic

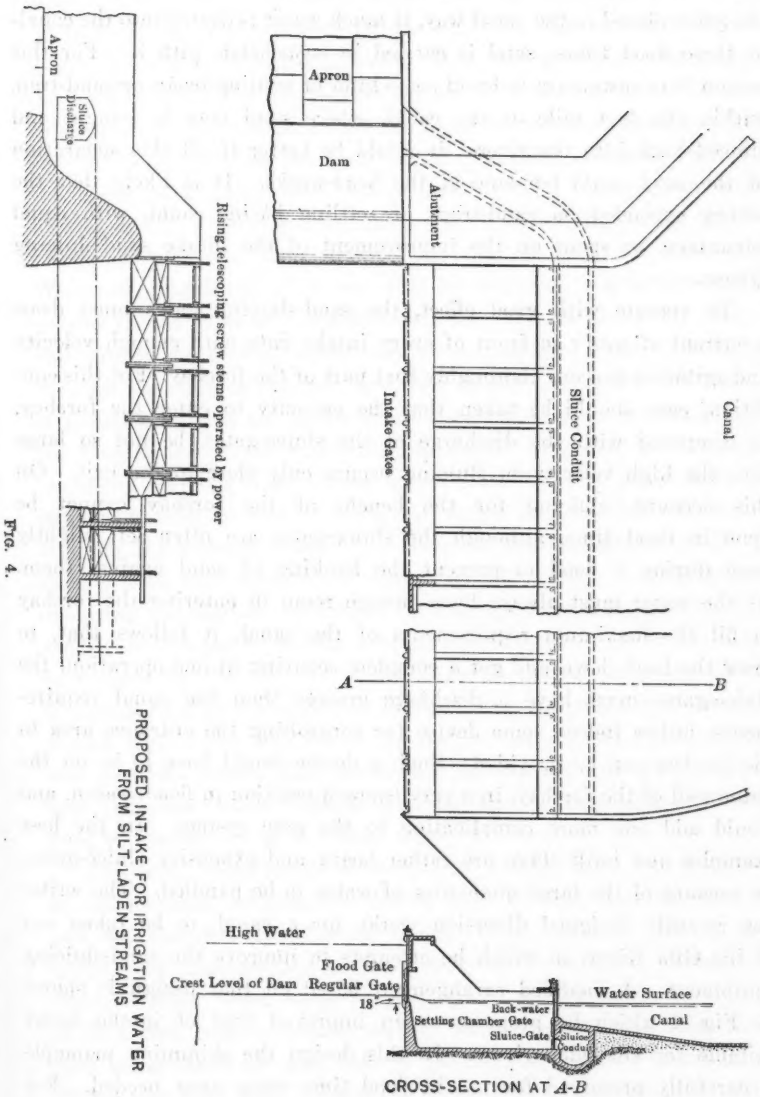

FIG. 4.

PROPOSED INTAKE FOR IRRIGATION WATER FROM SILT-LADEN STREAMS

piston, and a powerful rush of water washes out the sand. During a flood the water eddies about, and less sand is allowed to settle. With the gates placed in the usual way, if much water is drawn into the canals at these flood times, sand is carried in suspension with it. For this reason it is customary to build some kind of settling basin or sand-trap, within the first mile of the canal, where sand may be caught and sluiced back into the river. It would be better if all this separation of the sand could be done at the head-works. It is likely that the money expended on sand-traps or settling basins could, with equal advantage, be spent on the improvement of the intake sand-sluicing system.

To operate with good effect, the sand-sluicing gates must draw a current of water in front of every intake gate with enough velocity and agitation to scour thoroughly that part of the forebay. For this condition, care should be taken that the capacity to enter the forebay, as compared with the discharge of the sluice-gates, be not so large that the high velocity in sluicing occurs only close to the exit. On this account, sluicing for the benefit of the forebay cannot be done in flood time, although the sluice-gates are often left slightly open during a flood to prevent the banking of sand against them. As the water must always have enough room in entering the forebay to fill the maximum requirements of the canal, it follows that, to draw the level down and get a complete scouring at one operation, the sluice-gates must have a discharge greater than the canal requirements, unless indeed some device for controlling the entrance area to the forebay can be provided. Such a device would have to be on the outer wall of the forebay, in a very exposed position in flood season, and would add one more complication to the gate system. In the best examples now built there are rather heavy and expensive sluice-gates, on account of the large quantities of water to be handled. The writer has recently designed diversion works for a canal, to be taken out of the Gila River, in which he attempts to improve the sand-sluicing equipment. A modified arrangement based on that design is shown by Fig. 4 which he proposes as an improved type of intake works suitable for silt-laden rivers. In this design the skimming principle is carefully preserved for use in flood time when most needed. For the ordinary low-water conditions, the water is clearer, and is taken from the river over a series of wide, shallow crests, which reduce the

slope of the river bottom in the approaches to one so gentle that coarse materials will hardly be carried close to the gate entrances.

In flood times the forebay of the old type fills with gravel which is not easily sluiced out afterward. With the proposed arrangement, the lower part of the intake gate, called the "Regular Gate" is closed as soon as the flood rises 2 or 3 ft. above the crest of dam, and water for the canal is taken over the top of this gate, being controlled by the upper part, called the "Flood Gate", which closes down on the first as a sill. Gravel rolling along the river bottom during the flood passes on over the dam finding no place to enter or accumulate. Whatever gravel and sand does find its way into the intake gates is caught in the settling chambers (one for each intake gate) where it can always be sluiced under uniform conditions from the bottom, through the sluicing conduit, and back to the river below the dam. It is planned to have the upper leaf of the inside gates rise and cut off the back-water of the canal simultaneously with the opening of the lower, or sluicing leaf. These gates, however, can be worked independently, and, in case of need, the water may be shut off from the sluicing chambers entirely. It is believed that an intake of this type can be built and operated as cheaply as the other. A suitable power operating mechanism, which can be uncoupled for hand operation, can readily be designed for the proposed arrangement, as it has already been done for the old. It is also believed that sluicing the collected materials from one chamber of moderate size at a time, where a shallow stream with sharp fall can be secured to agitate and cut the deposit, will be more certain and thorough. All the sluicing gates discharge into the same waste conduit, as only one or two settling chambers need be flushed out at the same time.

The most satisfactory sluicing and intake gates yet devised are of the common rectangular sliding type, of cast iron or sheet steel, and operated by rising screw stems. They move on bronze sliding strips, and close on oak or metal sills at the bottom. Those at the Granite Reef Dam, built by the U. S. Reclamation Service,* are of thin cast iron, of arched section on the compression side, the tension being taken by steel rods at the back and placed across the bow of the cast-iron shell. They are light, strong, and durable. In this case, the sluice-gates are operated by hydraulic pressure pumps, the

* *Engineering News*, January 7th, 1909.

transmission being by heavy chains running over sheaves; they are weighted with concrete for closing by gravity. At the Granite Reef Dam, a very excellent feature of all the gates, which were designed by F. Teichman, M. Am. Soc. C. E., is that, on the pressure side, where sand, etc., is likely to bank against them, they present smooth fronts, instead of a system of deep ribs, as often built in the past.

In designing gates for these situations, the question of the proper coefficient of starting friction to use for the bronze sliding ways comes up. The writer's experience has shown that this coefficient is much larger than published authorities known to him would indicate. In order to make a reliable determination of the coefficient under actual working conditions, the writer disconnected the raising mechanism of a 5 by 7-ft. cast-iron gate, having machine-bronze sliding ways, in the power canal at Roosevelt, and in its place attached a long timber lever resting on a fulcrum made of a piece of round steel shafting held between flat steel plates. A platform for carrying weights was then suspended from a definite point on the lever arm, and the apparatus was used to weigh the starting resistance. The actual weight of this particular gate was known from the inspector's weight obtained at the time of its receipt from the manufacturer. The timber lever was weighed and its weight per linear foot assumed to be constant. A correction for the weights of the lever arms was then made.

Statement of Conditions of Test.—

Water pressure on only one side of gate;	
Size of gate opening	5 by 7 ft.
Area subjected to water pressure on the gate, measured on the center line of closing strips.	38.7 sq. ft.
Depth of water at sill of gate	8 ft. 8 in.
Head on center of pressure area	6 ft. 0 in.
Total water pressure on gate	14 500 lb.
Weight of gate	4 300 lb.
Sliding strips	Machined bronze.

Two experiments were made, as follows:

First Experiment.—To determine coefficient of starting friction after the gate had been closed tight for several weeks:

Result:	Frictional resistance	9 062 lb.
	Coefficient of starting friction	0.625

Second Experiment.—To determine coefficient of starting friction with the gate raised off the sill about ½ in. and water escaping under its lower edge:

Result: Frictional resistance..... 8 985 lb.
Coefficient of starting friction..... 0.62

The turbid condition of the water, perhaps, is the chief cause of the increased size of the coefficient.

In nearly all cases it would probably pay to use gasoline engine power for operating the gates. These engines are now so common that one suitable for the power required may always be found, and speed in opening and closing is essential. They should be designed in such a way, however, that hand power may be applied in case of necessity.

Trash-racks and booms, for protecting the gates from driftwood, have not been found necessary. Most of the driftwood comes down in flood time, and then it is nearly always carried in the middle of the stream and over the dam, as it collects in the stronger current in that part of the river. If the dam is placed below, or on, a sharp bend in the stream, which is not good policy, the drift, of course, will be thrown close to the outside shore and will need to be guarded against.

Special Cases.

In Arizona there is much more land fit for irrigation than can ever be properly irrigated from the flow of the streams of that State, and because of this abundance of land, as compared with the available water in the regular flow, it is always in order to look for storage opportunities along a stream. It sometimes happens that a natural storage basin may be found near enough to the head of the farming area to make the storage dam serve the purposes of a diversion dam as well. Diversion is then a question of conduits and gates for conducting the water past the dam and into the canals. As these conduits and gates are a necessary part of the storage dam in any case, they need not be noticed in detail in this paper.

Occasionally, water has been diverted from sandy-bottomed streams of steep grade by collecting it in perforated pipes or timbered conduits buried in the stream bed and brought to the surface by extending at a gentle grade far enough down stream to gain the necessary elevation.

Heavy floods will pass over an intake of this kind without damage, and a constant small flow can sometimes be obtained from the ground where the stream is ordinarily dry at the surface.

Fig. 5 illustrates a plan recently devised by the writer for a case on the Gila River where the area of the land under the canal would not justify the expense of a permanent structure extending entirely across the river bottom, which at this place is wide. The canal company has heretofore maintained at its head-works a brush and earth dam which has been carried away by small rises of water several times in a season. The great loss from this condition, as mentioned previously, is to growing crops which are deprived of water. The main object of the present plan is to provide an escape for the small summer rises in the river (say from 2 000 to 10 000 sec-ft.), which are of short duration, without at the same time losing the head necessary to keep the canal running. As the flow during winter floods, and an occasional summer flood, is very much greater than the foregoing figures, the dam, which raises the water only 3½ ft., is designed to go out automatically when the danger level is reached, thus largely increasing the discharge area and leaving no obstruction in the channel above the concrete foundations, which rise only to the natural bottom level of the river. When a flood has thrown down the dam, it will be comparatively easy to set up the steel frames again and put in place the planks which make the weir. The concrete foundation is on a bed-rock footing. It is expected that the earth dike, which closes the gap from the automatic dam to the farther shore, will be broken through by occasional extreme floods. It should be planted with willows or cottonwoods and Bermuda grass to help bind it together.

For the purpose of springing the latch which holds up the first 10-ft. section of the dam, it is proposed to have a protected well, connected with the river water, in the masonry of the abutment at the shore end, in which is enclosed a heavy float operating the necessary lever. The fall of the first frame is designed to trip the latch of the next, and so on until the fall of the dam is complete.

The individual planks of the weir are attached to a wire cable, the end of which is free at the point where the sections are first released, the other end being anchored to the opposite end pier. This precaution is taken to save as many pieces of this timber as possible

for use in replacing the dam after the flood has run down. It is expected that the string of planks will float and swing over to shore, where the lumber may be recovered.

It should be understood that the types of works mentioned in this paper are not advanced as suitable for all conditions to be found in Arizona. Every case must be considered in relation to its peculiar conditions and requirements. The Colorado River presents a series of conditions, due to its enormous volume of flood discharge, and to the conditions of its bed, that demand particular and unclassified solutions. For such water-sheds as those of the Gila and Salt Rivers, however, and for many other streams in the arid Southwest, it is believed the contents of this paper will apply. It will be observed that the best examples noted herein are structures put in by the U. S. Reclamation Service. These have been planned and constructed with an amount of care not often equalled in the case of structures built by private parties, and much valuable investigation and observation have been devoted to them.

STEEL STRESSES IN FLAT SLABS.*

By Dr. H. T. Eddy.†

The question of the percentage of reinforcement in flat slabs is important economically as well as theoretically. It is, moreover, a question respecting which there seems to be some misconception as to the principles which should be applied. Shall the concrete and steel be balanced as perfectly as possible; or, if not, which shall be made the stronger? The uninformed have usually insisted on over-reinforcement, so that the concrete would be the weaker. If it is possible to determine the actual stresses in the steel with precision, there is no doubt that slabs should be designed so that the steel will give way first. Concrete is an unreliable and fragile material compared with steel. Under-reinforcement, however, will make security depend on the steel, which has known properties capable of precise computation. When the steel begins to yield, that action will cause the concrete to fracture to some extent, but the structure will exhibit toughness, and will not be subject to sudden collapse. In case of over-reinforcement, where the concrete is crushed and gives way first, the structure is in danger of much more sudden and unforeseen failure.

That these conclusions coincide with those of economic design appears from the following consideration of the stresses in steel and

* This paper will not be presented at any meeting of the Society, but written communications on the subject are invited for subsequent publication in *Proceedings*, and with the paper in *Transactions*.

† Professor of Mathematics and Mechanics, Emeritus, College of Engineering, University of Minnesota.

concrete, as given by Turneaure and Maurer's equations for the equal resisting moments of steel and concrete per unit of width of slab regarded as a beam, namely,

$$M_s = f_s\, Ajd = f_s\, pjd^2, \text{ and } M_c = \frac{1}{2}\, f_c\, kjd^2,$$

in which $A = pd$ is the cross-section of the reinforcement per unit of width of slab, kd = the depth of the neutral axis, and jd = the depth of the steel below the center of compression of the concrete. As these moments are equal, the ratio of the stresses in steel and concrete is,

$$\frac{f_s}{f_c} = \frac{k}{2\,p},$$

in which p is the steel ratio of reinforcement. Using Turneaure and Maurer's tabular values of k, in case $n = \frac{E_s}{E_c} = 15$, and assuming that $f_c = 500$ lb. per sq. in., and $f_s = 16\,000$ lb. per sq. in., the values of stresses in steel and concrete, respectively, shown in Table 1, are found.

TABLE 1.

$n = 15$.		$\frac{f_s}{f_c} = \frac{k}{2\,p}$.	For $f_c = 500$ $f_s = \frac{250\,k}{p}$.	For $f_s = 16\,000$ $f_c = \frac{32\,000\,p}{k}$.
p.	k.			
0.0025	0.25	50	25 000	320
0.005	0.32	32	16 000	500
0.010	0.42	21	10 500	762
0.015	0.48	16	8 000	1 000
0.020	0.525	13	6 550	1 220

Table 1 shows how small the percentage of reinforcement should be (less than one-half of 1%) in order that, in case of under-reinforcement, the steel should be used with reasonable economy; also, in case of over-reinforcement, how great the stresses in the concrete become in order to develop the strength of the steel. Every consideration of correct design, safety, and economy seems to demand a very low percentage of steel, verging on under-reinforcement, rather than on any attempt at over-reinforcement.

If these principles are adopted as controlling the design of flat slabs, the all-important and crucial question is that of unit stresses in the steel. The writer hopes that the following discussions of tests

for actual stresses in several large buildings, as compared with computed theoretical stresses, may assist in supplying a satisfactory basis for computation and design such as has not been available hitherto.

The Northwestern Glass Company Building.

The mushroom, flat slab floor in the Northwestern Glass Company Building, in Minneapolis, Minn., was tested by Mr. F. R. McMillan, on May 12th to 24th, 1913. The pressure for immediate occupancy of the building by the owners was such as to compel the completion of the test at an undesirably early date after the slab, which had been frozen all winter, had sweated out, and had had an opportunity to commence to become cured. It is estimated that the condition of the slab at the beginning of the test was perhaps such as would be expected at the end of a period of 45 days favorable for curing.

Appendix A contains the particulars of the test conducted by Mr. McMillan, whose results are used in this discussion. The equations applied in the computations may be found in the writer's book, "The Theory of Flat Slabs."*

The maximum load on Panel D amounted approximately to 185 000 lb. This was placed on the four quarters of the panel, with open passageways, 1.5 ft. wide, across the middle of the panel each way, and with open spaces around the columns at each corner arranged so that only 181.5 sq. ft. of the total panel area of 16 by 17 ft. = 272 sq. ft., were actually covered by the loading. With such an arrangement of the loading it was difficult to determine just what should be assumed as the equivalent uniform load. The difficulty is increased by the fact that, no matter what load is placed on the mushroom heads, it will have little effect in increasing either stresses or deflections. Consequently, attention must be given principally to the equivalence of the loading not located over the heads.

The open passageways decreased the effectiveness of the actual loading, and the open spaces over the heads increased its effectiveness in a very complicated manner when one also considers their stiffness relative to the remainder of the panel area. It will be evident, however, that, on the whole, the loading as actually applied, was more effective in producing deflections and stresses than if the total actual

* The numbers of the equations in this paper are the same as those in "The Theory of Flat Slabs."

a value of W, somewhat different from that needed in computing stresses, might be required.

The writer has proposed the following equation

$$f_s = \frac{W\,L}{175\,d_1\,A} \qquad (34)$$

as giving the limiting unit stress in the rods of the side belts. In the present case this gives, for the rods of the short side belts,

$$f_s = \frac{200\,000 \times 16 \times 12}{175 \times 7.31 \times 1.6567} = 18\,000 \text{ lb. per sq. in.}$$

Two of the observed readings, on Fig. 4, namely, those at 3 and 10, amounted to 17 000 lb. per sq. in., and it is probable that if all the panels of the slab had been loaded at once with a uniform load of $W = 200\,000$, all these side rods would have shown nearly or quite the foregoing computed value of f_s. That this is so seems to be clear from the fact that these readings were taken in belts adjacent to panels which were not loaded, and that the stress at 10 under Load 3, when the total load was placed nearly equally on four panels instead of on two, was not much smaller than under Load 5. The changes in the stresses at 7, 8, and 9, between Load 3 and Load 5, lead to the

a value of W, somewhat different from that needed in computing stresses, might be required.

The writer has proposed the following equation

$$f_s = \frac{W\,L}{175\,d_1\,A} \qquad (34)$$

as giving the limiting unit stress in the rods of the side belts. In the present case this gives, for the rods of the short side belts,

$$f_s = \frac{200\,000 \times 16 \times 12}{175 \times 7.31 \times 1.6567} = 18\,000 \text{ lb. per sq. in.}$$

Two of the observed readings, on Fig. 4, namely, those at 3 and 10, amounted to 17 000 lb. per sq. in., and it is probable that if all the panels of the slab had been loaded at once with a uniform load of $W = 200\,000$, all these side rods would have shown nearly or quite the foregoing computed value of f_s. That this is so seems to be clear from the fact that these readings were taken in belts adjacent to panels which were not loaded, and that the stress at 10 under Load 3, when the total load was placed nearly equally on four panels instead of on two, was not much smaller than under Load 5. The changes in the stresses at 7, 8, and 9, between Load 3 and Load 5, lead to the same conclusions.

It will be seen, by comparing the observed stresses in the short side belt with those in the long side belt, that the latter were somewhat less than the former. This is the only kind of divergence between Equation (34) and experimental results which has come to the writer's attention. The divergence in this case appears to be due primarily to the nearness of these panels to the wall and to their position relative thereto.

Suppose a slab to be loaded in such a manner that the entire load was placed in continuous narrow strips, extending entirely across the middle of each panel, in a line parallel to the wall. These strips might be regarded as concentrated central loads on a wide beam having one end at the wall, with a depression or trough between the wall and the first row of columns parallel to it, another between the first and second rows, etc. These depressions would be much more pronounced than any crossing them perpendicularly to the wall.

The wall and Load 5 evidently had an effect of this kind, which caused the stresses in the short side belts perpendicular to the wall to exceed those in the long side belts.

TEST OF
NORTHWESTERN GLASS CO. BUILDING

FIG. 3.

Indeed, slab action in general may be described partly as the attempted mechanical superposition of one set of parallel depressions and elevations on another set of similar corrugations at right angles to them. Such sets mutually support each other and give rise to slab

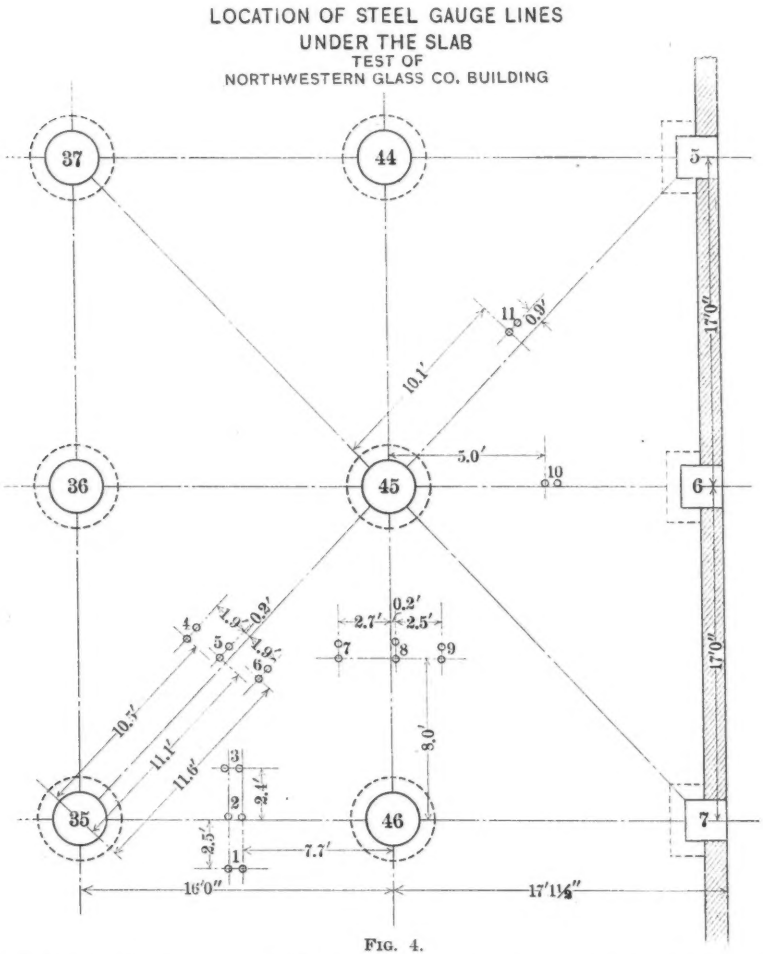

FIG. 4.

action, but any action which interferes with and disturbs the regularity of this superposition needs consideration. A wall support is such an interference, for it completely destroys the regular sequence of depressions and elevations at the end of one set and thus intensifies

those in the other set. The case just discussed is evidently of this character.

The writer has shown* that the stresses to be expected in the diagonals at the center of the panels are somewhat less than those in the middle of the side belts when all the panels of a slab are equally loaded.

By Equation (52) the unit stress in the middle rod of the diagonal at the center of the panel is

$$f_s = \frac{C_1 W L_1}{256 j d_2 A_1} = \frac{200\,000 \times 204}{256 \times 0.89 \times 6.94 \times 1.6567} = 15\,570 \text{ lb. per sq. in.}$$

The observed value at 5 in Panel D was 14 200 lb., which was larger than that in Rods 4 and 6 on each side of it, as required by theory. The stress at 11 in the wall panel, C, was larger, and amounted to 20 500 lb., which probably was due to the cantilever action at the wall being less than that exerted by the usual column heads.

Consider now the stress in the belt rods near the edge of the cap. In order to do this it is necessary to treat them somewhat more in detail than has been done in the writer's book, where the entire right section of diagonal and side belts has been regarded as unaffected by the mass of the cap, which forms a large boss, integral with the slab, and, as far as it extends, renders the belt much less extensible and compressible than it would be without it. The edges of each belt are so far from the edge of the cap as to permit of the assumption that the rods at the edge have the same stresses as they would were the cap not present; but those rods which are tangent to the cap will have their elongations and stresses reduced thereby, and the rods beside the cap and intermediate between these and the edges of the belts will have their stresses reduced in proportion to their proximity to the cap.

The case is different, however, with rods which cross the edge of the cap nearly perpendicularly. Although that part of the length of the rod which is inside the cap has its elongation prevented by the mass of the cap, the part outside must have its elongation correspondingly increased to compensate for this loss, and, on the whole, be equal to that of the rods beside it. The stresses in the middle rods of each belt, consequently, are increased abnormally for this reason just as it leaves the cap. Instead of attempting to determine this increase by

* "The Theory of Flat Slabs."

some intricate investigation, it will simply be assumed that the stress at this point in the middle rod does not exceed that in the outside rod of the belt at a point opposite the center of the cap. This must be very nearly the fact, and the stress in the outside rod at this point, as affected by the size of the cap, will now be considered.

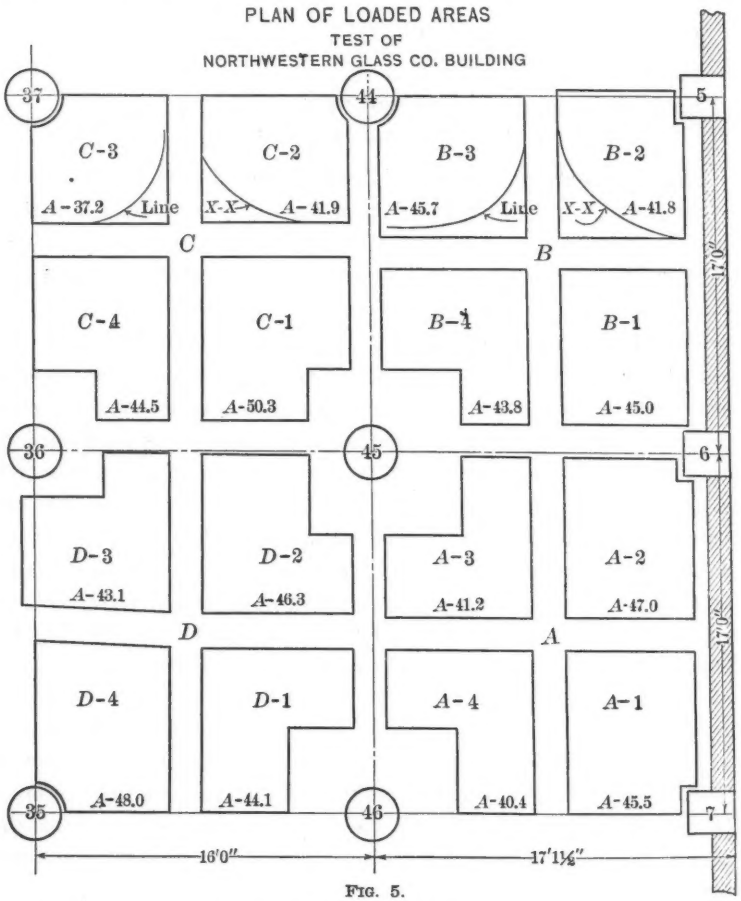

FIG. 5.

As the cap is integral with the slab and may be taken as horizontal at the edge of the cap instead of at the center of the column, as has been assumed in the writer's equations, the position of the points of inflection or contraflexure of the rods will be nearer the center of the

span than has been assumed in those equations, when account is taken of the size of the cap. In Equation (42), a stress equation, the position of the points of inflection of the side belts is determined to be at distances $\pm \frac{a}{\sqrt{3}}$ and $\pm \frac{b}{\sqrt{3}}$ from the middle of the span, because the belts are horizontal at the middle of the span and over the column centers. Now if, instead, the belt is horizontal at the middle, and at the edge of the cap, which, for convenience, is assumed to be square, the points of inflection will be at a distance from the mid-span of one-half the clear span between the caps multiplied by $\frac{1}{3}\sqrt{3} = 0.577$. Subsequently, this will be found to be in agreement with experimental determinations.

Instead of Equation (42), we shall have, for the limiting stress in the side belt rods opposite the column center

$$f_s = \frac{W L_1 (L_1 + L_2)}{800 d_3 A_1 L_2}\left[\frac{3 L_1^2}{B_1^2} - 1\right] \ldots\ldots\ldots\ldots (a)$$

To find f_s at any other point, put 2_x in place of L_1. This equation gives larger unit stresses in the side belt rods of the head than Equation (42), but will itself need to be reduced somewhat in case the belt under consideration has an unusual number of laps in the head. However, it leaves the unit stresses determined by Equation (34) unchanged. The reason for these larger stresses is the longer cantilever span due to the location of points of inflection.

As the law of the distribution of stresses in the rods of a diagonal belt differs from that in a side belt, where all the rods have an unequal stress, the writer will obtain an analogous value of the stress in the rods of a diagonal belt. Starting with Equation (39), which refers to the part of the panel forming the column head, and transforming to axes, x' and y', along the diagonals, as was done in Equation (47), an expression will be obtained which is identical with Equation (47), except that g will be replaced by $a + b$.* Hence, in place of Equation (49), we have for this area:

$$\pm e' = id\,\frac{\delta^2 z}{\delta x'^2} = \frac{(1 - K^2)\, q\, (a + b)}{24\, E\, j\, d_3\, \Sigma\, A}\left[a^2 + b^2 - 3\,(x'^2 + y'^2)\right]$$

*There is a misprint in the last term of Equation (47) in the writer's book, and $x'^2 + y'^2$ should be substituted for $x'^2 y'^2$.

FIG. 12.

In this, by Equation (41), $j \Sigma A = 6 A_1$. Introduce the effect of the size of the cap in the same manner as in Equation (a), derived for side belts, and apply it to find the stress at the edge of the belt opposite the column center, where:

$$4 x'^2 = L^2 = L_1^2 + L_2^2 = 4 (a^2 + b^2), 4 y'^2 = g^2$$

$$4 (x'^2 + y'^2) = L^2 + g^2 = L'^2, \text{ and,}$$

$$C_1 = \frac{1}{4}\left(\frac{L_1}{L_2} + 1\right)\left(1 + \frac{L_2^2}{L_1^2}\right) = 1, \text{ nearly, then,}$$

$$f_s = Ee' = \frac{C_1 W L_1}{400 d_3 A_1}\left(\frac{3 L_2^2}{B'^2} - 1\right) \ldots\ldots\ldots\ldots\ldots\ldots (b)$$

where B' is the clear span along the diagonal between the caps. This equation gives the stress in the rod at the edge of the diagonal belt opposite the column center, and this is assumed also to give the value of the unit stress in the middle rod of the belt just outside the circular cap. To find the stress at any other point, x' y', of the diagonal belt in the head, substitute $4 (x'^2 + y'^2)$ for L'^2.

It will be noticed that in the central area of the panel, where moments are positive, the stress in the diagonal rods is greatest in the middle rod, but, in the column heads, where moments are negative, the stress is greatest in the rods at the edge of the belt.

The value of the greatest tensile stress at the edge of a direct or diagonal belt, found from Equations (a) or (b), however, is computed on the assumption that the steel in the slab is practically at the same depth as the rods nearer the center of the same belt. Such, however, is not ordinarily the case. The edges of the belts near the cap lie at a somewhat lower level than the remainder of the belt, and, being nearer the neutral axis, the rods at the edges, for that reason, will not be subject to as large a stress as is computed from Equations (a) or (b), and may not have as large stresses as rods somewhat nearer the center.

In the rods of the diagonal belts, points of inflection and points of equal stress lie on circles with centers at the center of the panel, so that the points of inflection of the side belts which lie on lines perpendicular to the sides do not coincide with the points of inflection of the diagonal rods.

In this test no observations were made on the rods of the side belts by which any comparison can be made with Equation (a), but several points on the diagonals near the edges of the caps were ob-

served, which may be estimated by Equation (*b*), though no observations were made on the rods near the edges of the diagonal belts.

Under Load 3 it will be assumed that each of the four panels was loaded with what would be equivalent to a uniformly distributed total

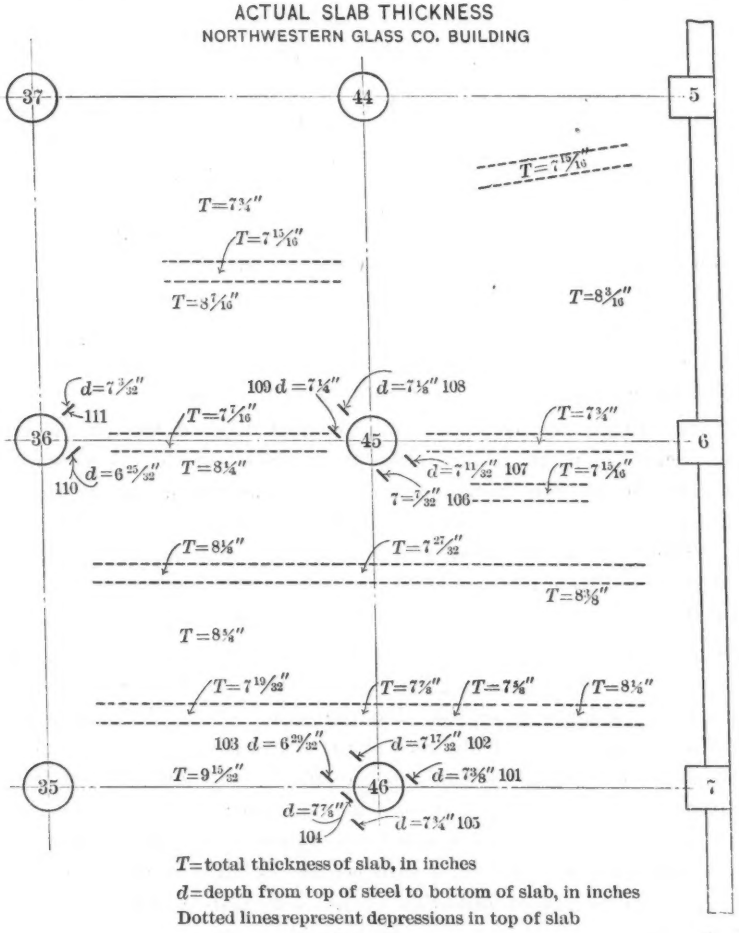

FIG. 13.

load of $W = 106\,250$ lb. By Equation (*b*) the limiting value of the unit stress in the outer rod is

$$f_s = \frac{106\,250 \times 204}{400 \times 6.5 \times 1.6567}\left(\frac{3 \times 86\,049}{60\,025} - 1\right) = 17\,000 \text{ lb. per sq. in.}$$

This is to be compared with the stresses observed on Fig. 3, most especially at 107 and 108, around the central cap of the loaded area, which were, respectively, 17 500 and 20 000 lb. Incidentally, comparisons should be made with observations at 102 and 111, at the caps on the edge of the loaded area.

Good agreement of the computed with the observed results is hardly to be expected in this case, because, just as the concrete was about to be poured, it was discovered that the radial elbow rods, by some mistake, had not been bent at quite the correct angle to correspond with the thickness of the slab, and it was necessary to pry the ends of the rods upward forcibly and hold them in this position by blocks under their extremities, thus putting them under considerable initial

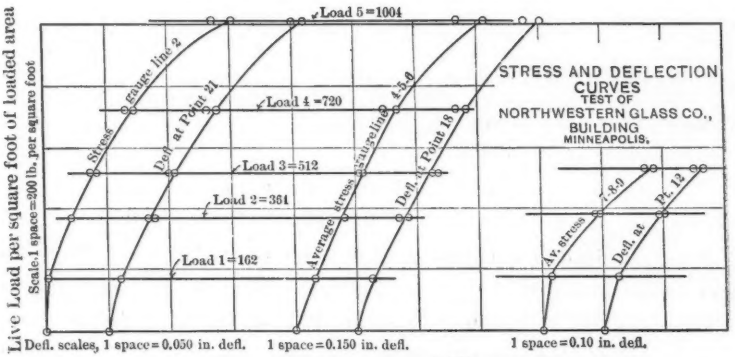

FIG. 14.

bending stress. The relief of this bending by the test load would influence the observations to some extent, and tend to make the observed values of f_s in the slab rods larger than those computed. At 111, Column 36, on the edge of the loaded area, the abnormal value of 22 400 lb. was reached under Load 3. Load 5 shows no such large increase over Load 3 of observed stress in the slab rods of the column heads in Panel D as was to be expected by practically doubling the loading. This fact is apparently inexplicable.

By reason of the disarrangement of the stresses due to initial bending, as mentioned, it seems to be impossible to trace the stresses in the slab rods in greater detail in this test than has been done already, where a satisfactory concordant maximum stress in the slab rods has

been reached. Consequently, a comparison of the computed with the observed deflections will now be considered. By Equation (71)

$$D_2 = \frac{W L_2 L_1^2}{4.4 \times 10^{10} A d_2^2}$$

in which $d_2 = 8 - 0.5 - 0.5625 = 6.9375$ in.

Hence $$D_2 = \frac{200\,000 \times 16 \times (17)^2 \times 1\,728}{4.4 \times 10^{10} \times 1.6567\ (6.9375)^2} = 0.4555 \text{ in.}$$

This agrees precisely with the value observed at 9 A. M. on May 18th under Point 18 at the center of Panel D. Practically the same deflection was found at the adjacent Point 17.

By Equations (61), (54), and (58), the deflection at the middle of the side belt is

$$D_1 = \frac{W L_1^3}{10^{10} A}\left[\frac{1}{10.7 d_1^2} + \frac{\frac{L_1}{L_2} + 1}{60 d_3^2}\right]$$

in which $d_1 = 7.31$ in. and $d_3 = 6.5$ in.

The values of the deflections are:

At Point 12: computed, 0.27 in., observed, 0.22 in.
" " 20 " 0.25 in., " 0.20 in.

The magnitude of the observed deflections in the side belts is less than those computed, for the same reason that the stresses are less, as before stated, although it is clear that the observed values would possibly reach those computed in case all the panels were loaded equally. This last remark is confirmed by considering the deflection under Load 3, which was nearly the same on all four panels, and equivalent to 106 250 lb., uniformly distributed, as found previously. The computed deflections would then be somewhat more than one-half of those already computed, and may be compared with the observed values, as follows:

At Point 12: computed, 0.15 in., observed, 0.16 in.
" " 20 " 0.13 in., " 0.13 in.

From which it may be concluded that the computed results would not be less than those observed if all the panels were equally loaded.

It seems clear that the continued increase of the deflection at Point 18 at the center of Panel D under Load 7 was influenced somewhat by the removal of the loading in Panel B, and that changes in the de-

FIG. 15.—SLAB REINFORCEMENT, NORTHWESTERN GLASS COMPANY BUILDING, MINNEAPOLIS.

FIG. 18.—TEST OF NORTHWESTERN GLASS COMPANY'S BUILDING BY MINNEAPOLIS BUILDING DEPARTMENT.

flections of adjacent panels may be looked for along the prolongation of diagonals rather than across the sides of the panels. This is perhaps the first test of a mushroom slab in which it has been possible to discover interaction of panels. Possibly, however, this may be due to the initial stresses in the radial steel previously mentioned.

Fig. 7 is of interest as showing the dissymmetry in the right and left half spans of the diagonals in Panels A and D. In A the supporting action of the wall along the entire length of the side evidently prevented deflection to some extent in the half span nearest to it, so that Point 9 was deflected less than the corresponding point in the other half span. In Panel D Point 18 was deflected less than the corresponding Point 16, because all the slab rods are lapped over Column 35, and none over 45, as may be seen on Fig. 1.

Owing to the irregularities of loading and variations of stiffness due to the inclusion of the wall panels, as well as accidental variations of stiffness of construction due to initial bending stresses, and also the inequalities of laps, it is too much to expect formulas derived for entire uniformity of loading and equality of panels to apply more closely than these comparisons show.

The Deere and Webber Company Building.

The test of the Deere and Webber Building, in Minneapolis, Minn., was made on October 30th to November 5th, inclusive, 1910, by Mr. A. R. Lord.* The panel dimensions are 19 ft. 1 in. by 18 ft. 8 in., the slab is $9\frac{3}{16}$ in. thick, and the concrete was only 40 days old on October 30th. All the slab rods are $\frac{7}{16}$ in. round, with twelve rods in each side belt and fourteen in each diagonal. The head steel consists of the rectangular diamond frame with four rods extending entirely across it, which was at that time the typical form used by the Leonard Construction Company in such buildings. The column caps are 54 in. in diameter and the slab rods of all belts are 7.25 in. from center to center, so that the side belts may be taken to have a width of 80 in. and the diagonals nearly 95 in. The mean size of the cap is 0.24 L.

Various loads, uniformly distributed, were applied simultaneously to eight panels, which, with the omission of one corner panel, filled

*Reported by Mr. Lord in a paper printed in *Proceedings*, Nat. Assoc. of Cement Users, Philadelphia, Vol. VII, 1911.

out a square of nine panels. This gave opportunity to observe stresses in the slab rods in one panel at the center which was surrounded on all sides by equally loaded panels.

This discussion will refer mostly to the results observed when the greatest load was on all the eight panels at once. This load had a mean intensity of 350 lb. per sq. ft. The area of a panel is $356\frac{2}{3}$ sq. ft., and the total load $W = 350 \times 356\frac{2}{3} = 124\,678$ lb. The depth of the embedment of the various rods observed is given in the report, but, as the rods of a belt act together, it is not certain that the embedment of individual rods should be used in the formulas. It has been assumed that the fair mean values are

$$d_1 = 8.5 \text{ in., } d_2 = 8 \text{ in., and } d_3 = 7.6 \text{ in.}$$

Applying Equation (34) to compute the unit stress in the slab rods on the short side of the panel at Point 14, of Fig. 3, in Mr. Lord's paper, which is the point where the greatest stress was found in any slab rod of a side belt between two loaded panels,

$$f_s = \frac{124\,678 \times 224}{175 \times 8.5 \times 12 \times 0.15} = 10\,000 \text{ lb. per sq. in.}$$

The observed stress at this point was 10 400 lb. The unit stress observed at Points 39, 40, and 14*a*,* on the short side belts, were somewhat less, but this is a satisfactory determination of the greatest stress at the middle of a short side belt.

Applying Equation (34) to compute the unit stress in the long side belt at Points 108 and 109,

$$f_s = \frac{124\,678 \times 229}{175 \times 8.5 \times 12 \times 0.15} = 10\,220 \text{ lb. per sq. in.}$$

The mean observed result was 6 600 lb. It is probable that this result, observed between two loaded panels bounded by panels not loaded, would be less than on the same belt in the two loaded panels beside it, on the principle that if only three successive spans of a continuous beam of many spans be loaded, the middle one will show less stresses and deflections than the end spans.

This, together with the fact that the inflection lines were much nearer to the center of the panel, was probably the reason that the observed result was so small. Apparently, however, there is no reason

*These refer to Fig. 3 of Mr. Lord's paper.

for the greatest unit stress being less on the long side of the panel than on the short side, when the belts are equal and the panels are so nearly square. In this particular the results of the test seem to be inexplicable unless the two bulkheads which extend nearly across the slab parallel to the long sides of the panels, one of which crosses the short side at 14, have this effect.

A similar discrepancy was found between the observed stresses on the long and short sides of the panel in other tests. It is certain that provision should be made on this long side for stresses at least as great as those on the short side.

Applying Equation (52) to the computation of the unit stress in the rods of the diagonal belt at the center of the panel at Points 3, 7, 110, and 12*a*, gives

$$f_s = \frac{124\,678 \times 229}{256 \times 0.89 \times 14 \times 0.15 \times 8} = 7\,440 \text{ lb.}$$

There seems to be some discrepancy between the table of numerical values and the plotted maximum stress at Point 12*a*. In any case, 12*a* shows abnormally large readings compared with the others, but the computed value just found is greater than three of the observed values and greater than the mean of all four.

The diameter of the cap being $0.24L$, the clear span between the edges of the caps on the side belt is $0.76L$, and the least computed distance of the points of inflection along the middle of the side belt is this divided by $\sqrt{3}$, or $0.577 \times 0.76L = 0.44L$; and, consequently, the distance between the points of inflection across the column center is $0.56L$, which, as stated by Mr. Lord in a second paper,* is precisely the observed position of the points of inflection in the side belt of this slab.

Applying Equation (*a*) to the computation of the unit stress at Point 205, Fig. 3, of Mr. Lord's paper, on the edge of the long side belt, gives

$$f_s = \frac{124\,678 \times 229 \times 453}{800 \times 7.6 \times 13 \times 0.15 \times 224}\left[\frac{3 \times 52\,441}{30\,625} - 1\right] = 20\,150 \text{ lb.}$$

per sq. in.

The value observed at 205 was 20 000 lb., and slightly less at the symmetrical position, 208, also situated at the edge of a short side

* Also published in *Proceedings*, Nat. Assoc. of Cement Users, Vol. VII, 1911.

belt. The corresponding unit stress in a rod tangential to the edge of the cap at 206 was less, for the reason previously stated, being only 14 400 lb. at 206, and 12 300 lb. at 209.

Applying Equation (*b*) to the computation of the limiting unit stress in the rods at the edge of the diagonal belt opposite the column center gives

$$f_s = \frac{124\,678 \times 229}{400 \times 7.6 \times 13 \times 0.15}\left[\frac{3 \times 111\,642}{70\,756} - 1\right] = 22\,440 \text{ lb. per sq. in.}$$

All the observed stresses were somewhat less than 16 800 lb., both at 202, the outside rod, and at 204, the rod tangent to the cap, and 18 300, at 203, the rod lying between them. The outside rod, for the reason already stated, did not show quite the computed stress, but the observed stress in the center rod of the belt, where it crossed the edge of the cap at 207, was 23 400 lb., when all the panels were loaded, and 24 200 lb. when half the load had been removed from the outer panels.

Applying Equation (71) to the computation of the deflections at the center of the panel gives

$$D_2 = \frac{124\,678 \times 224 \times 229 \times 229}{4.4 \times 10^{10} \times 64 \times 14 \times 0.15} = 0.248 \text{ in.}$$

Point 37, Fig. 3,* was the only center point observed in a loaded panel wholly surrounded by loaded panels. The mean value of seven readings was 0.224. When half the load was removed from the outside panels the deflection increased to 0.246 in. The mean readings at the centers of adjacent panels were: Point 4, 0.291 in.; Point 8, 0.306 in.; Point 12, 0.271 in.; all these being somewhat larger because adjacent panels were not loaded.

Applying Equations (54), (58), and (61) to the computation of the deflections at the middle points of the side belts gives $D_1 = 0.1555$ for the long side, and $D_1 = 0.1456$ for the short side. The only reading at the middle point of a long side belt not continuous with or contiguous to an outside panel was at Point 17 where the mean of seven readings was 0.1387. The mean reading at Point 5, at the middle of the continuation of the same rod on the other side of Column 41, between two loaded panels, was 0.229. These points were situated similarly to the middle points of three successive equally loaded spans

* Of Mr. Lord's paper.

of a continuous beam, Point 17 being at the middle point of the middle span, and Point 5 at the middle of one of the end spans; the first deflection was somewhat less, and the other somewhat greater than the deflection when many spans were equally loaded. Point 41 was situated so that its mean deflection should fall between that at 17 and that at 5, which is the fact.

Point 38 was on a short side, on a location in the middle span of three spans like that of 17 on the long side, and the mean reading was 0.127; Point 15 was on a short side, as 5 was on a long side, in an end span of three spans, and the mean reading was 0.163. The computed deflection falls between these, as it should. The deflection at 42 should fall between the readings for Points 38 and 15, which is the fact. Point 11 was in practically the same relative position as 15, and had equal deflections. Other deflections at the middle of outside belts had about half the preceding deflections, influenced more or less by their continuities.

The interaction of successive spans across the column heads, by reason of continuity of spans, is evidently of considerable amount in this floor. This is doubtless due to lack of stiffness at the junction between columns and slab, which in this design is almost entirely without stiffening rods, such as the elbow rods in the mushroom system. The very striking agreement of these computations with the observations in this test show that in all essential particulars the action of the reinforcement is in principle identical with that for which the equations here applied were originally developed.

The Larkin Building.

A very extensive and painstaking test of the Larkin Building, in Chicago, was made by Mr. A. R. Lord.* The design of the slab reinforcement in this building was of the general four-way type used in the mushroom system, but the column heads omitted much of the steel ordinarily used for stiffening the head, and, in place of it, resistance to bending and shear was supplied by a depressed head or "drop" of concrete, 8 ft. square and 6.75 in. thick, placed at the top of each column, between the cap and the bottom of the slab. This was made integral with the slab and formed part of it, just above the cap. The panels are 20 ft. by 24 ft. 2 in., or $L_1 = 290$ in., and

*The results were presented by Mr. Lord in a paper at the Ninth General Convention of Cement Users. Extracts from this appear in the *Cement Era*, January, 1913, p. 52.

$L_2 = 240$ in. The thickness of the slab proper is 9 in., except at the drop, where it is 15.75 in. The diameter of the cap is 60 in. The width of the side belts is from 90 to 93 in., and of the diagonal belts from 105 to 108 in. All the slab rods are $\frac{1}{2}$-in. round, 13 in each short side belt, 22 in each long side belt, and 21 in each diagonal belt.

The floor was designed for a dead load of about 120 lb. per sq. ft., and a live load of from 225 to 250 lb., with a maximum test load of twice the sum of these, or actually 738 lb. per sq. ft. As the dead weight of the slab was acting at all times, the stresses tabulated in the report are those due to the observed elongations plus corrections due to the weight of the slab itself, which is included in the 738 lb. The deflections given, however, are those actually observed under the loads applied, or a maximum test load for deflections of about twice 250 lb., plus 120 lb., or a total actual maximum load of 618 lb. per sq. ft. Hence the total maximum load producing stress was $W = 738 \times 20 \times 24\frac{1}{3} = 356\,700$ lb. The load was applied, and the readings of stresses and deflections were made at several stages. At Stage 2, 130 lb. per sq. ft. was applied over a test area of five panels, three of them wall panels, and two adjacent to them, not wall panels. In Stage 3 the load on this area was increased to 250 lb. In Stage 4, only three panels were loaded, two of them wall panels and one adjacent interior panel, with 415 lb. per sq. ft. Finally, in Stage 5, the entire load of 618 lb. per sq. ft. was placed on two panels only, one wall panel, and an adjacent interior panel, and these were situated so that their short sides were contiguous.

Apply Equation (34) to the computation of the unit stress in the rods of this short side belt, in which, ordinarily, it would be found that $d = 8.25$ in., but among the test data this is stated to have a value of 8 in. in this case. Hence

$$f_s = \frac{356\,700 \times 240}{175 \times 8 \times 13 \times 0.196} = 24\,000 \text{ lb. per sq. in.}$$

The observed stress was 24 200 lb., which would be decreased somewhat, as noted previously, if adjacent panels were also equally loaded, as contemplated in Equation (34). Applying Equation (34) to the long side belt,

$$f_s = \frac{356\,700 \times 290}{175 \times 8 \times 22 \times 0.196} = 17\,000 \text{ lb. per sq. in.}$$

The observed stresses in the rods of a belt lying between a loaded panel and one not loaded is much less than between two loaded panels. The observed value in this location is given at 10 200 lb., but it is not stated whether this is a mean value or the greatest value for any rod of the belt, or the stress in the middle rod. From the figured location of the test lines, it is probably the latter. The computed results should be regarded as in most satisfactory agreement with the observations.

Applying Equation (52) to the computation of the unit stress in the middle rod of the diagonal belt at the center of the panel:

$$f_s = \frac{356\,700 \times 290}{256 \times 0.9 \times 7.75 \times 21 \times 0.196} = 14\,070 \text{ lb. per sq. in.}$$

in which 7.75 in. is taken as the mean distance of the center of the steel from the upper surface at the center of the panel. The given observed value was 12 900 lb., which differs from the computed by less than 10 per cent. It is not stated whether the observation was in the wall panel or in the interior panel, or whether it was an average or in the middle rod of the belt, but it was probably the latter. If so, the stress in the middle rod should be greatest. This result may be regarded as satisfactory, and very near what would be observed in the middle rod if the adjacent panels were equally loaded.

Before computing the stresses in the head steel at the edge of the cap and edge of the drop, it should be noted that all the stresses given in the general summary of stresses for the maximum load of 738 lb. are from 2½ to 3 times as great as for the design load, which is half as great. This, among other things, signifies that the value of the modulus of elasticity for the concrete was much less under the test load than was its initial value. Under the test load of 738 lb., there is no one of the columns entirely surrounded by loaded panels. The consequence is that the observed stresses in all the belts of the head will be much less than those computed, and if an attempt were made to compute the stresses due to the design load which was spread over all the panels around the column, where most of the readings on the head belts were evidently made, the observed stresses would have to be multiplied by a coefficient of 1.5 or more to make them comparable with the results at the test load, 738 lb.

Now write Equation (*a*) in the general form

$$f_s = \frac{W L_1 (L_1 + L_2)}{800 d_3 A_1 L_2} \left[\frac{3 (2x)^2}{B_1^2} - 1 \right] \ldots\ldots\ldots\ldots (a)$$

in order to compute the unit stress in the rods of the long side belt at the edge of the cap, where $2x = B_1 = 290 - 60 = 230$ in., and $d_3 = 14$ in. The drop is so thick as to obviate mostly the increase of stress in the center rod where it crosses the edge of the cap, and therefore no account is taken of such increase. This unit stress is found to be $f_s = 9\,460$ lb. per sq. in. The observed stress along this side at the edge of the load, of course, was considerably smaller, and is given as 7 000 lb.

Making a similar computation at the edge of the drop on this belt, where $B_1 = 230$ in., $2x = 290 - 96 = 194$ in., and $d_3 = 7$ in., it is found that $f_s = 14\,500$ lb. per sq. in. Along this side belt at the edge of the load the observed result was only 10 400. The diagram of gauge lines seems to show that these are readings observed along the middle rod of the belt. In that case the outside rod at the edge of the belt under a load over many panels would have shown greater unit stresses than those computed, or, in the writer's opinion, at least as large.

Applying Equation (*a*) to the computation of the unit stresses in the short side belt at the edge of the cap, by exchanging the subscripts, 1 and 2, and placing $2x = B_2 = 240 - 60 = 180$ in., $d_3 = 14$ in., and $A_2 = 13 \times 0.196$, gives $f_s = 10\,950$ lb. per sq. in. This belt crosses the cap from the unloaded into the loaded area which covers the two panels on each side of it. The tipping of the head relieves to some extent the stresses which would exist were all panels loaded, and the reading given is 7 300 lb.

Again, compute the unit stress at the edge of the drop in this short side belt by inserting in the equation just used $B_2 = 180$ in., $2x = 240 - 96 = 144$ in., $d_3 = 7$ in., and $f_s = 15\,300$ lb. per sq. in. At this point there is something abnormal and inexplicable in the observed results which, apparently, should be larger than those observed at the edge of the cap where the concrete is so thick. This contradictory reading is only 5 800 lb., and may be due to some bend in the rod, or other peculiarity, because the same thing appears at the smaller loads.

Writing Equation (*b*) in the general form

$$f_s = \frac{C_1\, W\, L_1}{400\, d_3\, A}\left[\frac{3\,(2\,x')^2}{B'^2} - 1\right] \ldots\ldots\ldots\ldots\ldots (b)$$

and computing the unit stress in the middle rod at the edge of the cap on the diagonal of 21 rods by increasing B' between the corners of the assumed square caps and placing

$$L = \sqrt{290^2 - 240^2} = 320 \text{ in.}, \quad B' = 320 - 85 = 235 \text{ in.},$$
$$2x' = 320 - 60 = 260 \text{ in.}, \quad f_s \text{ is found to be as follows:}$$

$f_s = 12\,480$ lb. per sq. in. The necessarily smaller observed value was 10 800 lb.

Apply the same equation to compute the unit stress in the middle rod of the diagonal belt at the edge of the drop, assumed to be 96 in. in diameter because the projecting corner should be disregarded, and we have $2x' = 320 - 96$ in., $B' = 235$ in., $d_3 = 7$ in. Hence $f_s = 16\,160$ lb. per sq. in. The smaller observed value was 14 200 lb.

Applying Equation (70) to compute the deflection at the center of the panel gives

$$D_2 = \frac{W\, L_2\, L_1^2}{10^{10}\, A_1}\left[\frac{1}{6.56\, d_2^2} + \frac{1}{12.5\, d_3^2}\right]$$

in which the total load producing the observed deflection was 618 lb. per sq. ft., or a total load of $W = 296\,850$ lb.

$$D_2 = \frac{296\,850 \times 240 \times 290^2}{10^{10} \times 22 \times 0.196}\left[\frac{1}{6.56 \times 7.75^2} + \frac{1}{12.5 \times 14^2}\right]$$

or $D_2 = 0.41$ in. The observed deflections at Points 10 and 16 were 0.40 in., an extraordinary agreement, under the circumstances, of reduction of steel in the head and displacement of inflection lines which produce effects that tend to balance each other.

Deflections at the middle of the long side may be computed by Equations (91), (54), and (58), as follows:

$$D_1 = \frac{296\,850 \times 290^3}{10^{10} \times 22 \times 0.196} \cdot \frac{1}{10.7 \times 8^2} \cdot \frac{2.2}{60 \times 14^2} = 0.276 \text{ in.}$$

The observed deflections were 0.21 in. at Point 15 and 0.26 in. at Point 17, on the edges of the loaded area, which values would be somewhat increased if the adjacent panels were also equally loaded. A similar computation at the middle of a short side belt gives results still more in excess of the value observed at Point 13, Fig. 3, of Mr. Lord's paper,

by reason of the shortness of the concave section between the points of inflection. The surprising thing is, not that such discrepancies exist between computed and observed results, but that equations derived for a flat slab differing so widely and in so many particulars from this one should nevertheless be applicable at all.

The writer's equations were derived for the case of side belts with total cross-sections proportional to their spans and with diagonals with intermediate cross-sections which, according to his theory, is the correct proportion. The Larkin slab, however, has the cross-sections of its side belts proportional to the cubes of their spans, which is a highly uneconomical arrangement of steel, as shown by the unit stresses observed in the test. The fact that these equations apply so closely shows that the use of the drop in stiffening the head is practically identical in action with the steel frame of the column head which it replaces.

In view of the unqualified assertion made in the extract from Mr. Lord's paper in the *Cement Era,* respecting the Larkin test, that "the deflection readings, compared with those of other tests, show that the resulting structure is stiffer and stronger than the straight flat slab as ordinarily designed, with anywhere the same amount of materials", it becomes of interest to submit such a straight flat slab to analysis for purposes of comparison, as the writer's formulas are applicable to such a slab with considerable accuracy.

It is to be noticed that deflection readings do not of themselves permit any conclusions whatever to be drawn as to the strength of a structure, but have reference to stiffness only, so that that half of the assertion referring to strength is, on the face of it, unwarranted and entirely unsupported by these readings, and, in fact, will be found to be incorrect, as the writer will proceed to show. As to deflections, it may be that a perfectly flat slab might have a deflection of perhaps not more than 10% in excess of this slab, with its bulky and unsightly drop at the head of each column. If that should possibly be the case, it is a trivial matter, and of no consequence compared with the very serious loss of strength involved in this construction.

The volume of the drop, which is 8 ft. square and 6.75 in. thick, is 62 200 cu. in. In case this quantity of concrete were used to increase the mean thickness of the slab, it would make a flat slab approximately 0.9 in. thicker than at present. Such a flat slab 9.9 in. thick through-

out, with belts of 0.5-in. round slab rods, having 19 rods on each short side, 19 in each diagonal belt, and 22 on each long side, would have slightly less slab steel, and the same quantity of concrete in the slab as in the Larkin Building, but the maximum stresses in the steel would be far less.

The unit stress in the slab rods at the middle of the long side belt of this straight flat slab is found by Equation (34) to be

$$f_s = \frac{WL_1}{175\, d_1\, A_1} = \frac{356\,700 \times 290}{175 \times 9 \times 22 \times 0.196} = 15\,230 \text{ lb. per sq. in.}$$

Similarly, the unit stress at the middle of the slab rods in the short side belt is

$$f_s = \frac{WL_2}{175\, d_1\, A_2} = \frac{356\,700 \times 240}{175 \times 9 \times 19 \times 0.196} = 14\,600 \text{ lb. per sq. in.}$$

By Equation (52) the unit stress in the diagonals at the center of the panel is

$$f_s = \frac{W\, L_1}{256\, j\, d_2\, A_2} = \frac{356\,700 \times 290}{256 \times 0.89 \times 8.56 \times 19 \times 0.196} = 14\,400 \text{ lb. per sq. in.}$$

It would require a load of more than 1 200 lb. per sq. ft. on such a mushroom slab to produce a maximum unit stress on the slab rods as great as was caused in the Larkin slab by the test load of 738 lb. per sq. ft. The difference is so great as to nullify entirely any such unwarranted claims as those quoted in the extract from the *Cement Era*.

It thus appears that a mushroom slab more than 65% stronger than the slab in the Larkin Building can be constructed at the comparatively slight additional expense of part of the steel required for the radial and ring rods of the mushroom head. How much more steel might be required for the mushroom is unknown, because no data are available as to the quantity of steel used in the top rods which were embedded in the top of the slab over the column heads, and in the frame supporting the slab rods in the column heads in the Larkin slab. In Mr. Lord's paper a photograph of the steel in place for pouring the concrete shows a rectangular frame support of this kind. Any claim for superiority of the Larkin structure with reference to strength and economy of materials over a properly designed "straight" flat slab is, in the writer's opinion, wholly without foundation.

The Donnelly Building.

The Donnelly Building, in Chicago, Ill., was designed and tested by Mr. A. R. Lord. Certain data of this test, as yet unpublished, have been put at the writer's disposal by C. A. P. Turner, M. Am. Soc. C. E. The panels in the slabs are 24 ft. 10 in. by 24 ft. 4 in. and 11 in. thick, with a drop of concrete at the head of each column, 9 ft. square and 9 in. thick, integral with the slab. The total thickness of the slab at the edge of the cap is 20 in.; the effective thickness from the center of the reinforcement in the head to the lower surface of the slab is 18 in.

Design load, 300 lb. per sq. ft.;
Weight of slab, 150 lb. per sq. ft.;
Test load, 750 lb. per sq. ft.;
Area of panel, 604.3 sq. ft.;
$L_1 = 298$ in.;
$L_2 = 292$ in.

All the reinforcement was of ½-in. round rods. Each long side belt had 26 rods, and each short side belt and diagonal belt, 25 rods. The computed maximum unit stress at the center of the short side belt, by Equation (34), is

$$f_s = \frac{292\ W}{175 \times 25 \times 0.196 \times 10.25}.$$

For a working load of $300 + 150 = 450$ lb. per sq. ft., $f_s = 9\,000$ lb. For the total test load of double this quantity, that is, 750 lb. per sq. ft., in addition to the weight of the slab itself, $f_s = 18\,000$ lb. when all the panels are equally loaded.

The deflection at the center of the panel may be computed for the test load of 750 lb. per sq. ft. by Equation (70) as follows, by assuming $\Sigma A = 6A_1$ as the reinforcement in the area over the head of the columns, this being 80% of that assumed in the standard mushroom design:

$$D_2 = \frac{604.3 \times 750 \times 292 \times 298^2}{10^{10} \times 25 \times 0.196}\left[\frac{1}{6.56 \times 9.75^2} + \frac{1}{10 \times 18^2}\right] = 0.384 \text{ in.}$$

The observed deflection was barely 0.3 in., which shows that the lines of inflection in this design were somewhat nearer the center of the panel than assumed in Equation (70), as they were also in the Larkin Building.

If a straight mushroom slab be designed with the same quantity of concrete in it as the Donnelly slab, the drop will furnish sufficient concrete to make the slab 1.2 in. thicker, giving a total thickness of 12.2 in. The computed stress at the middle of the side belts, in case all the slab belts remain unchanged, will be $f_s = 16\,100$ lb., instead of 18 000 lb. under the test load, and the computed deflection will be barely 0.4 in. at the center of the panel.

The Donnelly slab has a 9½-ft. square frame of 1⅛-in. round rods to support the slab rods in each head, which, with the lap, is more than 40 ft. long. A standard mushroom head would require more steel than this for radial and ring rods, but the quantity is very small compared with its considerable increase of strength, and this without increasing the deflection beyond a very conservative and in every way permissible value. Therefore, a straight flat slab design, such as the mushroom, appears to be preferable to one with a large drop like this. Means for making a rational comparison not having been available heretofore, it has not been possible to state positively that the unwarranted claims that have been made for designs with a large drop were unfounded; but that such is the fact is now demonstrable, as appears from the foregoing computations.

The St. Paul Bread Company Building.

The floor of the St. Paul Bread Company Building is a rough slab, 6 in. thick, and has 16 by 15-ft. panels, reinforced with ⅝-in. round rods, ten in each belt. The design load was 100 lb. per sq. ft. The slab, Fig. 19, was constructed in winter and frozen, but, as the final test was postponed until August, 1912, the slab was very fully cured, considerably more so, in fact, than most slabs when subjected to test. The test was made by Professor W. H. Kavanaugh, of the University of Minnesota, in the following manner:

First, extensometer measurements were made on seventeen 8-in. lengths of slab rods, which were exposed under a single loaded panel, three of these, Nos. 1, 2, and 3, being at the middle of three rods of one long side belt at the edge of the load, and the remaining fourteen distributed over the central area of one diagonal belt. Second, measurements of deflections were made at two points, one at the center of the panel and one near the middle of the interior edge of one long side belt. Third, the embedment of the rods was tested. Table 2 con-

tains the observed elongations due to change of loading at all the seventeen positions for each of the test loads, 108.4, 316.8, and 416.8 lb. per sq. ft., as well as after the removal of the load. A comparison of the observed elongations at symmetrical points reveals such discrepancies in the observations as to require some preliminary discussion.

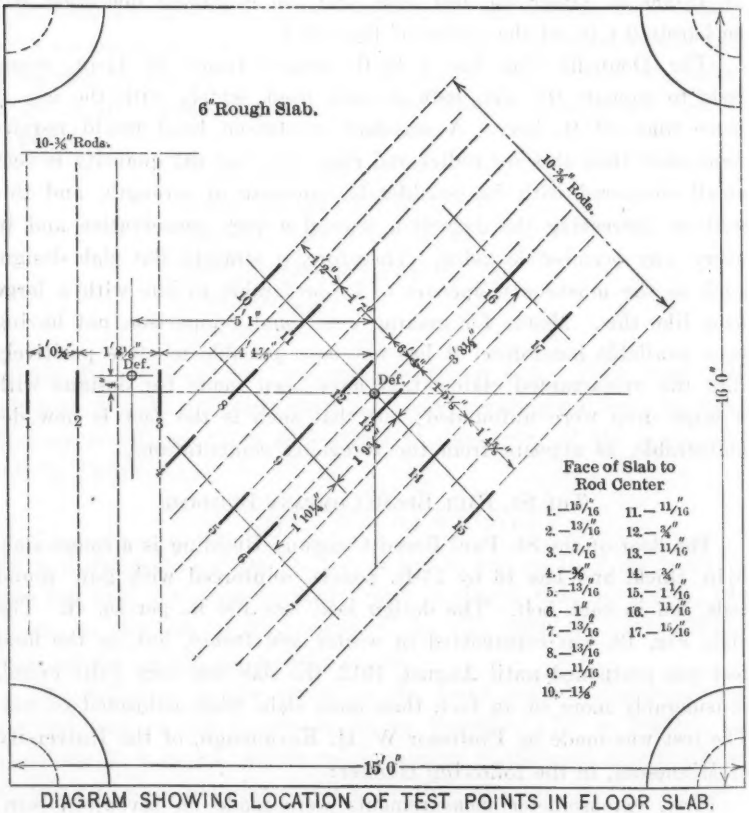

DIAGRAM SHOWING LOCATION OF TEST POINTS IN FLOOR SLAB.

FIG. 19.

Observations Nos. 5 and 6 were on a pair of diagonal rods on each side of and adjacent to the diagonal line of the panel, there being no rod exactly on the diagonal, and situated just beyond the edge of the other diagonal belt. No reason can be discerned for any difference between these elongations, but the wide

difference that appears must be due to some peculiarity in one of the rods, such as a crook or bend, or some lack of homogeneity in the concrete. Comparing Observations Nos. 5 and 6 with Nos. 4, 10, 15, and 16, which, being at about the same distance from the center, should, by Equation (49), have about the same elongations, it is found that No. 5 is abnormally large, and at the same time No. 16 is abnormally small. No. 8 is another set of abnormal results, which is evident from the fact that, being midway between Nos. 4 and 11, its elongations should lie between them; it is larger than it should be, with a final compression after removing the load. Nos. 7 and 17 should be the same, and Nos. 4 and 17 should be alike. The varying embedments of the portions of this rod which were observed show that there was probably a kink in it, which might account for the observed discrepancies. It is possible, however, that some such differences may appear when the loading is piled on one side of the panel before piling it on the other. No such explanation, however, will fit the case of Nos. 12 and 13, which are at the middle of the two rods adjacent to the diagonal line at the center of the panel. There appears to be no question that No. 13 is abnormally large, for No. 12 agrees well with others, being only a little larger than those at the nearby positions 9, 11, and 14, and the values at No. 13 are in wide disagreement with them. The

very considerable differences between results which should apparently be equal makes it evident how inexact single determinations must often be by reason of bends in the rods, lack of homogeneity in the concrete, etc., and emphasizes the importance of carefully laying belt rods straight and having them spaced uniformly, as well as embedded equally, before pouring the concrete, if consistent results are desired. It also shows the importance of checking all readings by readings at symmetrical positions.

It may be stated in general that the observed unit stresses and the deflections in this test are less than they would be for a slab tested at the stage of curing at which tests are usually made, a stage to which the equations apply more precisely. In consequence of this, all the computed results will exceed to some extent those actually observed.

Apply Equation (34) to compute the unit stress at Nos. 1, 2, and 3 of the long side belt. Assuming $d_1 = 5.3$ in.,

$$f_s = \frac{100\,000 \times 192}{175 \times 5.3 \times 1.1} = 18\,800 \text{ lb. per sq. in.}$$

in case of many panels equally loaded. The mean observed unit stresses for three rods at the edge of the load was 17 190 lb., the stress in each of the rods being practically the same, a fact that speaks well for the stiffness of the head. The computed unit stress at the center of the panel is

$$f_s = \frac{100\,000 \times 192}{256 \times 0.9 \times 5 \times 1.1} = 15\,150 \text{ lb. per sq. in.}$$

The observed unit stress at No. 12 was 12 000 lb., though at No. 13 the abnormal value of 19 600 lb. was found.

As the observations of stresses and deflections were made when only a single panel was loaded, and the computations assume that all the panels are equally loaded, any very close agreement of Table 2 with the observed results is not to be expected; nevertheless, comparison with that table shows that the computed results agree with the observations far better than the observations agree among themselves at such symmetrical points as admit of any comparisons.

The deflection at the center of the panel under a load of more than double the design load plus once the dead load, namely, 316.8 lb. per sq. ft., was 0.32 in., which is less than $\frac{1}{800}$ of the diagonal span. To

compute the deflections at the panel center, apply Equation (71), as follows:

$$D_2 = \frac{100\,000 \times 180 \times 192^2}{4.4 \times 10^{10} \times 5 \times 1.1} = 0.56 \text{ in.}$$

Computation of the deflection at the point near the middle of the interior edge of a long side belt gives a deflection for a load of 100 000 lb. on each panel of approximately 0.4 in.

TABLE 3.—DEFLECTIONS, IN INCHES, UNDER GIVEN LOADS PER SQUARE FOOT.

		Test Loads, in Pounds.			
		108.4	316.8	416.8	0
Center of panel	Observed	0.077	0.320	0.437	0.155
" " "	Computed	0.146	0.426	0.560	.....
Edge of side belt	Observed	0.065	0.247	0.332	0.124
" " " "	Computed	0.104	0.304	0.400	.....

As before stated, the somewhat large excess of computed over observed deflections is due to two circumstances: first, and principally, to the age and consequent stiffness of the slab; and secondly, at the edge, to the fact of a single panel load instead of many, neither of which circumstances is taken account of in the equations used.

THE STUDEBAKER AUTOMOBILE BUILDING.

The Studebaker Automobile Building, Michigan Avenue and 21st Street, Chicago, Ill., was erected in 1910, and is an example of a system of construction with two-way reinforcement only. The distances between column centers are 24 ft. and 23 ft. 9 in. Papers descriptive of this system may be found in the current technical journals.* All these papers, except the second, were written by T. L. Condron, M. Am. Soc. C. E., whose company designed the Studebaker Building. The last paper gives the results of tests of this and other buildings built on this system, while the second and third papers give the sizes and quantities of steel reinforcement in this particular building, from which it appears that the weight of steel reinforcement per panel was 2 600 lb.

Two kinds of floors are constructed on this two-way system; one is a perfectly flat slab of uniform thickness throughout; the other has

*Journal, Western Society of Engineers, December, 1909: *Engineering Record*, January 22d, 1910; *Engineering News*, January 27th, 1910; *Western Contractor*, March 12th, 1913.

a large so-called "panel" in the ceiling in the middle of the space between each four columns. The Studebaker Building is of this second kind, so that in the middle of each panel proper, 24 ft. by 23 ft. 9 in., there is this architectural "panel" about 18 ft. square. The thicker parts of the slab, extending from column head to column head, thus constitute shallow girders which in this case are 12 in. thick and about 6 ft. wide; and the central panels, 18 ft. square, are only 6 in. thick, giving a mean thickness of slab of 8.6 in., if the same quantity of concrete were uniformly distributed.

The design load was 100 lb. per sq. ft., and the dead load of the slab itself was also assumed at 100 lb. per sq. ft. The test load was applied on a single panel, and, in accordance with the Chicago Ordinances, amounted to 300 lb. per sq. ft., or a total of $300 \times 570 = 171\,000$ lb. This caused a deflection at the center of 0.34 in.

This floor will be compared with a mushroom slab, 8.6 in. thick, designed to carry the same loading.

The Studebaker slab had a thickness of 1 in. of concrete clear under the $\frac{3}{4}$-in. square girder rods, and $\frac{3}{4}$ in. clear of concrete under the $\frac{1}{2}$-in. round rods at the bottom of the central panel. The mushroom slab will be assumed to have twenty-five $\frac{3}{8}$-in. round rods in each belt, and 0.6 in. of concrete clear under the rods at the bottom of the slab, it being customary to make this fire-proofing layer less for smaller rods, and in any case not less than 0.5 in.

By Equation (34) the stress in the side belt under the dead load of 100 lb., plus the test load of 300 lb. per sq. ft., will be

$$f_s = \frac{228\,000 \times 288}{175 \times 7.8 \times 2.76} = 17\,400 \text{ lb. per sq. in.}$$

Mr. Condron states that he has used 17 000 lb. as the unit stress in the steel. Under a working load consisting of 100 lb. dead load plus 100 lb. design load the stress would be one-half the value computed above, namely, 8 700 lb. per sq. in.

The quantity of slab steel per panel in this design depends somewhat on the length of lap in the splicing. Without any lap, there would be in each 24 by 23.75-ft. panel:

Side rods,	25×24	= 600	ft.
Side rods,	25×23.75	= 594	"
Diagonal rods,	50×33.75	= 1 687.5	"
Total length of $\frac{3}{8}$-in. round rods		= 2 881.5	ft.

The weight of this is $2\,881.5 \times 376 = 1\,081.5$ lb. In round numbers, it will be assumed that the steel in the mushroom head, consisting of radial and ring rods, will bring the total weight up to 1 300 lb. per panel, which is just one-half that in the Studebaker Building with the same quantity of concrete.

Now, as to deflections: by Equation (71), the central deflection due to the test load is

$$D_2 = \frac{171\,000 \times (288)^3}{4.4 \times 10^{10} \times 2.76 \times (7.4375)^2} = 0.594 \text{ in.}$$

If the cross-section of the steel were doubled throughout, the deflection would be one-half of this, or 0.297 in., which is only slightly less than 0.34 in., which was the central deflection observed in the Studebaker test.

It will be noted that the formulas in the writer's investigations are dependent on the quantity of reinforcement, and not on the directions in which it runs, the only condition being that the belts shall cross in such immediate proximity to each other as to make their mutual action on each other effective. This does not occur with perfect uniformity everywhere in the two-way system under consideration, and, consequently, it would be expected to show somewhat greater deflections with the same quantity of steel than would the mushroom system.

The special claim made for this system by its designers is that in it the stresses in the steel reinforcement can be readily computed by the method of moments due to the loading. No tests have been published, so far as the writer knows, to substantiate this claim, and in his judgment such tests would show a difference, between extensometer observations and those obtained by the formulas published in the papers previously referred to, of not less than 50% of the observed amount, and probably more nearly 100 per cent.

This conclusion is based not only on the general theory of such structures, with which the writer has some familiarity, but on the computations just given in this paper, which fairly support this statement.

APPENDIX A.

Extracts from Report of Test of the Northwestern Glass Company Building.

By F. R. McMillan.

Description of the Building.—This is a four-story-and-basement warehouse, of the skeleton type of reinforced concrete construction, erected for the Northwestern Glass Company, of Minneapolis, from plans prepared by Bertrand and Chamberlin, Architects, and Mr. C. A. P. Turner, Consulting Engineer. In plan it is 66 by 163 ft., divided into 16 by 17-ft. panels. The floor is of the "Mushroom" type of flat slab construction, designed for a live load of 400 lb. per sq. ft. The 8-in. rough slab is reinforced with fifteen $\frac{3}{8}$-in. round rods in each direct and diagonal belt, as shown on Fig. 1. At the time of the test, the 2-in. cement finish which is to form the wearing surface was not in place.

Age and Conditions of Curing.—At the time of the test, the concrete in the test panels had been in place 5 months, but the weather had not been favorable for curing, except during the last few weeks. On the day the test panels were cast, December 6th, 1912, the mean temperature was 10°, with a maximum of 19° and a minimum of 0° Fahr. From this time until the end of March, 1913, the temperature practically remained below freezing. The usual precautions were taken to prevent freezing of the green concrete. Salamanders were kept burning in the basement until January 10th. The slab was kept covered with boards and canvas from the day it was poured until the erection of the forms for the second floor was begun. This interval was about a week or 10 days. Pouring of the second floor was begun on December 28th, and from this time until January 10th salamanders were kept fired under the second floor. The forms supporting the test panels were removed near the end of February. The last few weeks before the test the weather was very mild, and it is said that the concrete showed a noticeable increase in hardness during this period. At the time of the test, May 12th to 19th, the floor had all the appearance of an excellent hard concrete.

Plan and Description of the Test.—As the time available for the test, and the floor space that could be occupied in the basement, were limited by the necessity of caring for large shipments of glass, attention was confined to the measurement of deflections and deformations at critical points only. Very little choice was had in selecting points on the upper side of the slab at which to determine steel extensions;

for, with the type of extensometer used, measurements could only be taken on the top belt of rods and at points very near the surface.

Extensometer measurements were taken at various stages during the loading and unloading, and in all but one instance they were taken immeditely after each load was in place and again just before applying the next load. Deflections were taken at a number of intermediate stages at which no extensometer measurements were made. The extensometer measurements were made with the regular short-legged laboratory form of Berry strain gauge, reading over an 8-in. gauge line. The deflections were measured with a portable instrument specially designed to enable measurements to be taken at a large number of points without obstructing passage under the various panels.

The test load was of cement in bags, arranged in four piles in each panel, separated by aisles to prevent arching and to facilitate the taking of observations. The entire four panels were first loaded uniformly in three stages up to a total load of 540 lb. per sq. ft. of loaded area. The load from two panels was then nearly all transferred, in two stages, to the remaining two panels, making an intensity of 1 000 lb. and 750 lb. per sq. ft. on the loaded areas of these two panels. The removal of the load was made by stages in such a manner that the one panel retained its full load of 1 000 lb. per sq. ft. for 68 hours. The detail of areas and intensities of loading are shown on Figs. 5 and 6.

The accompanying tables and drawings show all the data of loading and the resulting steel stresses and deflections. These are self-explanatory. The steel stresses have been calculated from the extensometer measurements on a basis of 30 000 000 lb. per sq. in. for the modulus of elasticity. Fig. 13 shows the actual thickness of the test slabs and the depth of the rods at the top on which extensometer measurements were made.

MODERN PIER CONSTRUCTION IN NEW YORK HARBOR.

Discussion.*

By Charles W. Staniford, M. Am. Soc. C. E.†

Mr. Staniford.

Charles W. Staniford, M. Am. Soc. C. E. (by letter).—Some of the discussion has wandered into questions not germane to the subject matter of the paper, and has entered into matters pertaining to harbor design and general methods of construction.

The particular object of the paper was simply to show what had been accomplished by the Department of Docks in producing something more permanent than the ordinary New York wooden pier, and at about the same cost.

It is the writer's opinion, however, that all the discussions are valuable, as they bring out many admirable points in connection with harbor design and general designs for actual construction.

It is repeated that the old wooden pier, as built in New York Harbor up to 10 years ago, because it was easily removed and reconstructed, was one of the greatest factors in developing the harbor facilities. Instead of the shipping being compelled to adapt itself to the location and operation of massive permanent structures located along the water-front, as in English and Continental harbors, where there are stone quays and piers, the structures for berthing vessels and taking care of cargoes in New York Harbor were located to meet the conditions of shipping as these conditions developed and increased facilities were required. As the size of the vessels increased, the docks grew larger, in width as well as length, in proportion to the width of the slips, that is, the distance between piers increased to accommodate the greater beam of ocean steamers. It can readily be

* Continued from November, 1913, *Proceedings*.

† Author's closure.

Mr. Staniford.

seen that if the New York water-front was lined with a system of massive and permanent stone, steel, or concrete structures, the development of the harbor could only proceed at enormous expense, and consequently with much less rapidity than is made possible by building structures of lighter form. The type formerly built by the Department met for the time all requirements, but, at little added expense, many objectionable features of the former construction have been eliminated, thus doing away with constant repairs; and, for the present, at least, the Department has a type which is durable and at the same time inexpensive, and admirably meets the present-day demands of shipping. The result of this more modern method of construction has been shown in the paper, and the figures substantiating the statements are based on fact, not conjecture.

Mr. Harris questions the lasting qualities of the asphalt wearing surface, and infers that a 3-in. deck sheathing would outlast the asphalt. The experience of the Department with deck sheathing is absolutely as cited in the paper, and not a matter of inference. Repairs to New York piers are absolutely needed at short intervals, resulting in frequent renewal of the whole deck sheathing, the wear on the latter being the result of a traffic movement probably unequaled in the world. In fact, this whole paper deals with conditions of this kind, where structures are under intense use constantly, and not with docks built in Navy Yards or in any place for public function, where team traffic is almost unknown, or where the docks are practically intended as a berthing place for steamers while undergoing repairs.

As a concrete illustration of the inexpensiveness of the asphalt wearing surface, the piers of the Chelsea Section may be cited. On these nine piers, each approximately 800 ft. long and 125 ft. wide, asphalt wearing surfaces were laid, and for a period of 5 years, under the most extreme traffic conditions, no repairs were necessary. Under the contract for this work, 96 989 sq. yd. were laid, and a bond for 5 years was given to maintain the asphalt wearing surface; at the expiration of this 5-year bond period, repairs were only needed on 780 sq. yd., costing $800, or less than 1% of the total cost. From the expiration of the bond period to the present day no repairs of these surfaces have been necessary; and, furthermore, no repairs are needed at the present time. Fourteen other piers may be cited where the same result has been secured by the use of asphalt.

As stated in the paper, for light traffic, this asphalt wearing surface may be eliminated, but, for heavy traffic, it has been found absolutely necessary to put some deck wearing surface over the concrete; and in some other localities the writer has advocated wood block or brick pavement for this purpose. Granite block pavement has been considered, but was not adopted because it would add so much to the weight.

Mr. Stanford.

Mr. Harris questions the facility of making repairs to decks of this kind. These repairs, like all others relating to dock and harbor structures, must be made by specialists in work of this class. The Department force, consisting of twenty pile-drivers with their crews, is constantly engaged in doing just such work.

It is mentioned that the eventual destruction of caps and stringers by continuous repairs deserves consideration. This is just what was considered in the design of piers of this style. By eliminating all the stringers and all the deck, leaving practically little more than the timber caps, the quantity of timber to be renewed is reduced to an absolute minimum, the life of the caps, in addition being prolonged considerably by the use of the new system with its water-proof deck. In time, when repairs to this composite structure are required, owing to the rot of this insignificant quantity of timber underneath, such repairs will not necessitate the disturbance of the concrete deck, as all the work may be done below it by simply supporting the structure between alternate pile rows, removing the caps, and bench-capping

Mr. Staniford.

the piles, the usual method by which similar repairs have been made by the Department for 25 years or more.

The repair of an occasional pile in the interior of the pier, on account of rot, is accomplished without any trouble by cutting the pile and replacing the head by bench-capping or splicing, thus making the structure as strong as the original. This has been done in a number of instances in New York, even under elaborate buildings, such as ferry houses, without any trouble whatever, and without any interruption of traffic.

The design of this pier offers relief from constant repairs, and makes unnecessary the expense of actual reconstruction from mean low water up, for the experience with the asphalt deck surface has covered a sufficient time to prove that repairs have been greatly eliminated by this feature, and the structure is actually preserved by the asphalt deck surface.

The writer gave what he considered to be full recognition to the design of the piers being built in the Brooklyn Navy Yard, as being a good type for producing an absolutely permanent structure in these waters. To produce anything in the line of permanent development, however, is simply a question of expense. Mr. Harris has given some figures relative to the cost of piers in South Brooklyn, and has inferred that these prices were not a fair criterion, it being contended that the piers were built at extremely low cost, and with no profit to the contractor. This contention is difficult to prove. In the paper, the cost data for these piers are correct, and are repeated and elaborated as follows: The 31st Street Pier was let to the lowest bidder at $174 587. This was one of twelve bids, the next four higher being: $183 820, $192 462, $195 897, and $196 725. The 33d Street Pier was let to the lowest bidder at $236 500. This was one of seven bids, the next three higher being: $244 587, $246 332, and $254 897.

In each case the bidders for these piers were among the most reliable dock-building contractors in New York; and without question, any one of them could have performed the work successfully for the amount of his bid.

The New York Department of Docks has developed many designs for absolutely permanent structures, not only on the lines of the piers in the Brooklyn Navy Yard, made permanent from low water up, but absolutely permanent structures with concrete piles, and various forms of filled-in piers, some of which are without doubt as good as those cited. In any event, no two designs are exactly the same. Where the money is available, and the cost of deck repairs will necessarily be slight, and where a permanent structure is warranted, Mr. Harris is unquestionably right in suggesting that the structure should be made permanent from low water up.

Mr. Staniford.

Mr. Harris states that the generally accepted opinion that there are no marine borers in New York Harbor is in error. He states that they are found in the Lower Harbor, and that perhaps under certain conditions they may develop with wind and tide on the South Brooklyn shore. The writer fails to see why he cites the fact that he had found sea borers at Fort Lafayette. This question of the presence of the teredo, limnoria, or other wood-boring animals was settled by the Department more than 40 years ago. In fact, it was not only settled by the Department, but by all the corporate interests which have helped to build up New York Harbor while spending several hundred millions of dollars in building wooden structures. Unquestionably, if New York had remained a settlement with none of the evils attendant on the growth of a city of even ordinary size, these wood borers would have remained in the harbor, and the present form of construction would not have obtained. This has not been the fact, however, and 30 years ago the last evidences of the activity of these animals disappeared in all pier construction built either by the City or by others in the Upper Harbor.

In presenting this pier as a type of construction for New York Harbor, the writer took it for granted that it would be understood as applying to piers to be built in the harbor proper, and not for outlying sections nearer the ocean, where, of course, the teredo exists, this form of sea life requiring clear and fresh salt water in order to live. These wood borers have long been driven from the harbor proper. Even 10 years ago, the Department, in approaching the zone of danger (at the end of the Lower Bay) adopted the plan of creosoting all piles, but even in such localities, namely, along the northerly shores of Staten Island, at St. George, and other places where the teredo had been somewhat active, untreated piles which had been in the water for 8 years have been pulled and have shown absolutely no sign of any wood borers.

Before determining to use timber in the South Brooklyn Section, the Department for a number of years made a most exhaustive investigation, with divers, of hundreds of existing piers, bulkheads, and other structures along the water-front, looking for signs of infection by the teredo. The result showed that, although this sea worm had been somewhat active there in years past, it is now practically extinct.

Furthermore, for years past, the Department has been continually repairing the older structures built by the City. In the course of these repairs, the renewal of piles, even in the older structures, is found necessary only at rare intervals in the interior of the piers where they have been protected by the timber deck; though near the sides, where exposure is greater, more extensive repairs are needed. Also, the Department is continually removing old structures, some of them the oldest in New York Harbor, to make way for improvements. In these

Mr. Staniford.

removals every pile is examined, under orders, for any evidence of the teredo, in order to obtain some idea of the time when it disappeared from that particular locality. In some instances the piles show that they were attacked by the teredo in the olden days, but, probably on account of increasing pollution of the water, it had ceased to exist. Piles removed from structures built within the past 25 years are as good as the day they were driven, and are constantly used again in other work.

Recently, the Department has been removing some of the old Brooklyn ferry houses on the East River, these structures being among the very oldest on the water-front. In pulling the piles, each was examined with particular care to see if the teredo had made any ravages, but no evidence was found in any case.

The following is a concrete example of the wonderful preservation of these piles and the non-existence of the teredo. When the old Pennsylvania Ferry House, at the foot of Cortlandt Street, one of the oldest structures along the lower water-front near the Battery, was being removed, the writer visited the premises in order to determine whether it would be advisable to use some of the old piles, which happened to be in the right position to take their place as part of the grillage for the concrete retaining wall which was to run under the new ferry house. He found that the piles, cut several feet above low water, were in a remarkably good state of preservation; the foreman, on being told that the piles were as good as the day they were placed, replied, "They are better than the day they were driven." They were subsequently retained and remained in the permanent structure as specimens of absolutely perfect piles, thus saving the cost of placing a number of new ones.

Mr. Snow says:

"There are many examples of concrete construction in sea water in Boston Harbor, and in every instance known to the speaker there has been serious disintegration between high and low tides."

In New York this condition does not obtain in the concrete works produced by the Department of Docks. A few other concrete bulkheads have disintegrated in this way, notably at the Brooklyn Navy Yard, where such a bulkhead, approximately a mile in length, has entirely disintegrated and been removed. The last piece of this concrete wall is now being demolished near the end of the Cob Dock, where absolute disintegration has taken place throughout, extending many feet back from the face, including the front piles, ends of caps, etc.

It is presumed that the Government will replace this wall with a new concrete structure, and then all the old Navy Yard concrete wall will have been reconstructed.

Up to the present time there has been no failure in any part of more than 8½ miles of concrete and granite wall construction, built

by the Department of Docks and Ferries, during a period of more than 40 years. Mr. Staniford.

Frank W. Hodgdon, M. Am. Soc. C. E., Chief Engineer of the Massachusetts Board of Harbor and Land Commissioners, writes as follows:*

"Practically all the structures built of concrete in Boston Harbor have been badly disintegrated between high and low-water marks."

To this the writer replied as follows:†

"That it will be of interest to your readers is evidenced by the fact that this office is in continual receipt of letters of inquiry from all parts of the world, not only from harbor engineers, but from engineers engaged in the design of bridges in order to ascertain the condition of such work built of concrete in salt water, in view of the failure of such structures throughout the world.

"It certainly is a question concerning which engineers should receive all information possible whereby people at large may receive due consideration in assuming the financial responsibility in future for constructions of this kind which are supposed to be built with a view to permanency.

"I will not attempt to give the history of anything but city construction work in New York Harbor, and the condition of same at the present time. Most of the work done here during the past forty years has been done by the Department of Docks, or what is now known as the Department of Docks and Ferries of the City of New York. During this period the city has been engaged in the construction of a permanent sea-wall, located principally around lower Manhattan, below 80th Street. This has been added to recently by quite extensive construction at North Brother Island, in the Borough of the Bronx, at Whale Creek in the Borough of Brooklyn, and at the Gowanus Section, South Brooklyn.

"This sea-wall in a general way varies in type of construction, according to the character of foundation, but the essential features above the foundation are very similar in all types. Almost every type of bottom is encountered in New York Harbor, while the wall has been built to meet these varying conditions, about twenty-five different modifications having been used thus far in the foundation work to meet the conditions imposed. There are three general types, however; one built upon solid rock, one built upon hard bottom, such as good, stiff clay or compact sand, and one built on soft river mud, forming a wall supported by mud flotation.

"In many parts of the waterfront of Manhattan, for instance, bedrock is over 200 ft. below the river bottom, overlaid with soft mud. In the rock sections the wall has acquired a height above the rock as much as 50 ft. In other rock sections the wall is founded upon rock that has had to be blasted in order to create a sufficient depth for wharfage in front, and to take off sufficient rock for a stepped-off bottom in order to safely found the wall against the slope of the natural rock.

* *Engineering Record*, June 10th, 1911, p. 655.
† *Engineering Record*, August 5th, 1911, p. 176.

Mr. Staniford.

"In the soft mud bottoms the longest piles are used. In most types requiring pile foundations, the piles are usually cut off at a depth of about 15 ft., below mean low water, and from the top of these piles the wall proper is built.

"In the case of the rock bottom type the wall proper may be considered to commence at the top of the bag foundation which is built immediately on the rock bottom to a proper grade, for receiving the wall proper. From the tops of these pile and concrete bag foundations, the wall is built up to the vicinity of mean low water of concrete blocks, varying according to design from about 20 to about 95 tons in weight. These concrete blocks are moulded in air in mould boxes and are shipped on scows from the yard at which they are fabricated to any point on the waterfront where they are to be used. For handling these blocks we use two derricks, according to weight of block, a 40-ton derrick and a 100-ton derrick.

"Above these blocks the type of construction is generally the same, consisting of four courses of granite facing, of headers and stretchers, dove-tailed into a thick backing of concrete deposited en masse in the rear of the granite, and all carried up to the grade for the granite coping. In several places concrete deposited in situ forming a homogeneous mass with the concrete backing is substituted for granite and carried up to the coping course. This is usually done at points particularly where piers project from the bulkhead, as this portion of the wall is covered by the pier and, therefore, not visible. This type of construction with concrete face, instead of granite face, appears also in the general construction of the Claremont Section, the 116th Street Section, the Gowanus Section in South Brooklyn, the Whale Creek Section in Brooklyn, the Fulton Section on the lower East River, and part of the Old Slip Section on the East River.

"All of this wall construction has been built in the river itself, generally well off from the shore, in salt water, in a tide with an average range of 5 ft., varying in extremes to 8 ft. The tidal and current conditions in most parts of the East River waterfront are so severe that a diver is not able to stand up and work for more than half an hour in slack water, necessitating the construction of temporary breakwater barriers as a protection for the diver and for work against the current.

"The Department of Docks and Ferries, up to the present time, has built about 8¼ miles of this river or sea-wall, requiring in its construction in the neighborhood of 6 000 concrete blocks. In the course of years the Department has had many opportunities for examining the condition of this wall in connection with the building of sewers, etc. Up to the present time no disintegration has been discovered that can be attributed to the existence of the structure in salt water. The concrete itself is in an admirable state of preservation, absolutely hard, and is undergoing no regular process of disintegration. In some cases between high and low water marks, where the concrete has been deposited in situ, there are indications of ice abrasions, but nothing whatever to cause any softness or to expect ultimate trouble.

"In some cases there are indications of the effect of wave action or scour on the freshly deposited concrete within the tidal range, due

CONCRETE BLOCKS BUILT AND PLACED IN WALL BY DEPARTMENT OF DOCKS, AND REMOVED BY THE EDISON COMPANY IN THE CONSTRUCTION OF INTAKE TUNNELS.

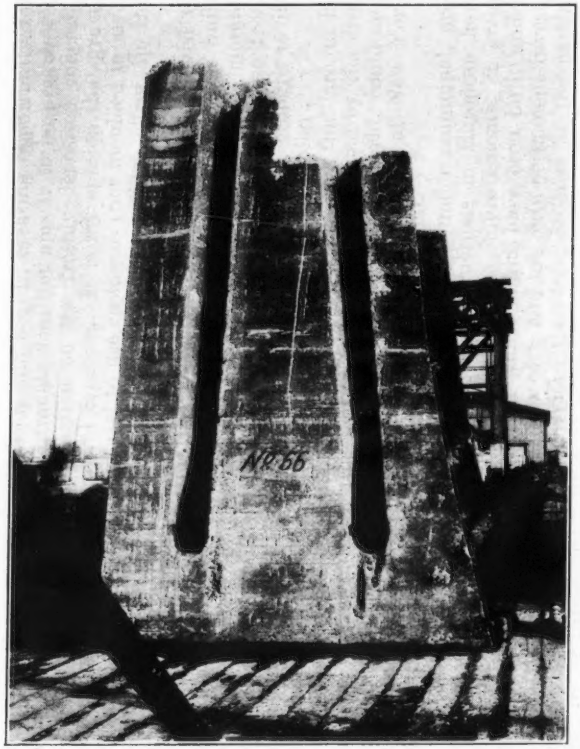

FIG. 13.—END VIEW.

FIG. 14.—BACK VIEW.

Mr. Staniford.

to carelessness in work on the mould boards, creating opportunity for tidal or wave scour, but this trouble does not appear to be progressive after the original scouring action on the freshly deposited concrete, excepting in the case of gravel concrete. It is my opinion that gravel concrete is not a proper material to use en masse (not moulded in air), where it is to be subjected to wave action or tidal effect in the process of depositing.

"Up to the present time the Department has not been obliged to spend much money on repairs to the sea-wall. This wall was built to be permanent, and at the present day all of the exposed concrete, which in the course of a few years may become a little worse from abrasion than at the present time, can be repaired and brought to its original state with the expenditure of a few hundred dollars.

"The extreme conditions that exist in Boston and that are to be seen in certain parts of this harbor, outside of work done by the city, and, in fact, in all of the various harbors of the world, could not exist and continue in the municipal work of the City of New York under its present financial control and government.

"Concrete harbor works built in other cities under municipal, private or corporate control, as well as constructions in European harbors, were, of course, all built originally as improvements, at great expense, over timber construction which might have been built under ordinary expenditure at a far less cost, and are only permanent investments, according to their behavior; therefore, because of the partial failure or threatened failure of so much concrete work in harbor construction, leading engineers throughout the world are assuming unusually expensive construction in their endeavors to produce permanency, by going to the other extreme and using granite or stone.

"Notwithstanding the failure or partial failure of concrete in the presence of salt water, in certain localities, the fact remains that this sea-wall which has been under construction by the City of New York for 41 years, is at the present time an excellent piece of work and is subject to the same climatic conditions as all cities on the Northern Atlantic Coast with the attendant ice, cold and rain characteristic of this latitude."

With reference to the concrete blocks mentioned by Mr. Betts as having been removed from the bulkhead wall after immersion in the salt water of the harbor for 10 years, Figs. 13 and 14 are submitted. These are from photographs of the blocks after they had been removed from the wall at 38th Street, East River, and placed on the Department Dock at the East 24th Street Yard. These blocks, weighing about 80 tons each, and recorded as Nos. 66 and 82, respectively, were fabricated on June 20th and August 16th 1902, and were set in the East 38th Street bulkhead wall on July 14th and August 30th, 1902. They were removed from the wall by the Edison Company, in the construction of intake tunnels, on October 31st, 1912.

The abrasions along the top and parts of the bottom edges of these blocks are the result of chiseling, in taking the blocks out of the wall and breaking their contact with the concrete backing and

Mr. Staniford.

granite which surmounted them. They are in a perfect state of preservation, showing no disintegration, even to the extent of the displacement of a particle. The edges are practically knife-edges, and the sharp-cut ridges along the joint lines of the mould boards show clearly. These blocks will be used in other work of the Dock Department when convenient.

Mr. Taft has presented a design for a permanent concrete dock which no doubt would answer for some localities where the bottom would permit of constructing a foundation such as he recommends. It is novel in many of its features, and has many good points; but the question of decreasing the thickness of slab in the type of deck now being built by this Department would not be considered here. This is a question that cannot be decided analytically, but must be answered by experience with structures subject to the heavy side shocks which piers receive, together with the shocks from traffic, and from merchandise falling while being handled on the pier. The slab described in the paper has been tried out and its thickness is slightly greater than that used in the original piers; any future change, if ever made, would be to increase it.

It may be interesting to many of the members of the Society to mention that another governing principle with the Dock Department engineers, in evolving a type of pier leading to the use of a reinforced concrete deck, was the elimination of any possible patented process. Municipal contracts in New York must be prepared so as to avoid the use of any patented processes, in order that competitive bids may be received to produce the structure under the design presented. This is not only a barrier, but is troublesome throughout the whole preparation of the contract and while the work is under construction. The Department, therefore, has evolved a type which, at least, has not caused any trouble from this source; it simply calls for a prescribed size of rod and spacing, or their equivalents in other shapes, on which a bid can be made by anybody manufacturing steel for reinforced concrete.

Mr. Taft's type, however, has many good features, and might well be used by private corporations desiring a permanent structure, the writer's only objection to it being the thin slab for heavy traffic. This is not such a serious factor as to detract from its usefulness, as the necessary increase in the thickness of this slab would not add greatly to the cost, although Mr. Taft makes quite a feature of this.

FLOOD FLOWS.

Discussion*

By Robert E. Horton, M. Am. Soc. C. E.

Mr. Horton.

Robert E. Horton, M. Am. Soc. C. E. (by letter).—On page 1057,† Mr. Fuller states that:

"As far as the writer knows, the first suggestion of the use of the element of time in a formula for flood flows was made by Allen Hazen, M. Am. Soc. C. E., in a memorandum written by him in 1910."

It is not disputed that the idea of the use of the element of time in the discussion of flood flows may have occurred to Mr. Hazen independently, but in deference to the late George W. Rafter, M. Am. Soc. C. E., the writer feels obliged to deny that the idea originated with Mr. Hazen. This idea, as to its application to floods and also to other hydrological data, was suggested to the writer at least as early as 1896, or 14 years before it was suggested to Mr. Fuller by Mr. Hazen.

It was Mr. Rafter's desire that the writer should prepare the data for a paper on the application of the Theory of Probability to Flood Flows and other hydrological data, and the matter was discussed frequently and fully during the years 1896 to 1904. It appeared at that time, however, that stream flow data were so meager as to make it desirable to defer the completion of the studies. The writer continued the studies, as occasion arose, using the ordinary law of probability where the data were too meager to permit of plotting a satisfactory special probability curve on logarithmic paper.

* Continued from December, 1913, *Proceedings*.

† *Proceedings*, Am. Soc. C. E., May, 1913.

Mr. Horton.

In 1896 the writer had prepared, at Mr. Rafter's request (by letter dated October 25th, 1896), an analysis of the rainfall and run-off of the Upper Hudson Drainage Basin, in which the probable average interval of recurrence of run-off less than the observed minimum was determined by the Theory of Probability. This and similar phenomena were analyzed by the ordinary method of probability, through the use of the so-called Gaussian Law of Error.*

It was recognized at that time that the Gaussian Law did not represent accurately the law of frequency of recurrence of many hydrological events, and an effort was made first to find a better general law† and to deduce individual laws. For the latter, the method of plotting flood records on logarithmic paper was tried, and proved so promising that, between 1900 and 1908, many logarithmic probability curves were plotted by the writer and corresponding formulas deduced, involving time as an element; and the methods and results have been applied extensively in professional practice by the writer for a period of several years.

He also applied the method of analysis of flood data by logarithmic special probability curves to the determination of maximum navigable stages, capacity of waste-weirs, etc., in connection with his work as Resident Engineer in Charge of the Bureau of Hydraulics of the New York State Barge Canal.

These results, after discussion with other engineers of the Department and with the Advisory Board of Consulting Engineers, were used as a basis in the design of work costing some millions of dollars. In this work the writer adopted 100 years in most cases as the average interval of recurrence of a flood of the magnitude to be made the basis of design. For the determination of relative frequencies of floods of different magnitudes on small torrential drainage basins in the Upper Mohawk River area, for which flood records were mostly wanting, the writer used as a basis of comparison in 1906 logarithmic flood discharge formulas which he had previously deduced for the Neshaminy, Tohickon and Perkiomen, as follows:

$$Q = 30\ T^{0.25} \text{ for the Neshaminy,}$$
$$Q = 30\ T^{0.27} \text{ " " Perkiomen,}$$
$$Q = 40\ T^{0.25} \text{ " " Tohickon,}$$

in which Q = flood discharge equalled or exceeded in an average interval of T years, in cubic feet per second per square mile.

These formulas were based on 20 years' records of the streams, covering the period, 1885-94. They give the results shown in Table 37.

* Report of State Engineer and Surveyor of New York, 1896, p. 841 *et seq.*

† In a letter dated August 11th, 1897, Mansfield Merriman, M. Am. Soc. C. E., suggested to the writer the use of a function of the form $y = (x + a)^2 (x - b)^2$ for this purpose.

Mr. Horton.

The writer also deduced the following general formula, applicable to these and similar drainage basins:

$$Q = 4\,021.5\frac{T^{\frac{1}{4}}}{A},\quad T = \sqrt[4]{\frac{Q\,A}{4\,021.5}}$$

or, as a logarithmic formula,

$$\log.\ Q = 3.6043881 + \frac{1}{4}\log.\ T - \log.\ A,$$

in which A = drainage area, in square miles; other notations as in Table 37.

TABLE 37.

Stream.	Drainage area, in square miles.	Interval, T, in Years.				
		1	10	25	50	100
		Cubic feet per second per square mile.				
Perkiomen	152	29.7	49.6	60.5	70.5	82
Neshaminy	139.3	29.4	55.0	71.0	85.5	104
Tohickon	102.2	40.5	71.0	89.0	105.0	125

In view of the foregoing considerations, the writer fails to discover wherein there is any proper basis for a claim of originality for this method, as far as the use of time as an element in flood formulas is concerned, as set forth in the paper. The writer does not claim any great breadth of applicability for the general formula just given, but believes that factors other than area modify the flood discharge of streams so profoundly that it is better, wherever possible, to derive individual formulas or flood-frequency diagrams for each stream. Following this idea, he deduced flood-frequency diagrams in 1906-08, for use in connection with the New York Barge Canal work, for the Mohawk, Hudson, Oswego, Seneca, and other streams. He has deduced and used similar special probability curves and logarithmic formulas to determine the law of frequency of recurrence of various other hydrological events, such as minimum seasonal rainfall, duration of periods without rain, relative probability of floods in different months of the year, minimum run-off of streams, storage volume required to maintain a constant supply from a stream, rain intensity of various durations, etc.

Attention may properly be called to another study, utilizing the same principles, which seems to antedate Mr. Hazen's suggestion of 1910, namely, the rain intensity diagram and formulas of J. de Bruyn-Kops, M. Am. Soc. C. E., for Savannah, Ga.*

* *Transactions*, Am. Soc. C. E., Vol. LX, p. 248.

Mr. Horton.

With reference to the Neshaminy, Perkiomen and Tohickon flood formulas derived by the writer in 1904, as given in Table 37, it should be noted that these were derived in such a manner as to include all floods exceeding a given magnitude, and not merely the greatest single day's flood of each year. The writer's usual method of deriving a formula for the frequency of annual floods which will equal or exceed a given limit is similar to that described in Table 5, Part *c*, except that in his analysis Mr. Fuller discards all floods less than the mean, and works from ratios. The writer utilizes all annual floods, both greater than and less than the mean, although it is sometimes necessary to use a different flood formula for floods of low intensity. He also prefers to work directly from the original data rather than by reducing the data to the form of ratios.

Mr. Fuller says of his general formula, as given on page 1014:*

"$Q = CA^{0.8}$ $(1 + 0.8 \log. T)$, in which Q is the largest 24-hour average rate of flow to be expected in a period of T years."

Tracing out the derivation of this formula (given on pages 1023-1027*), it appears that Q is there defined as the "average maximum flood," and the meaning of this term appears to be quite different from that first given.

Assuming that Mr. Fuller's formula represents the average magnitude of floods having an average interval of recurrence greater than T, it may also be said that it represents the magnitude of a flood which will be equalled or exceeded at some average interval greater than T, but that this interval is unknown and cannot be determined from his formula. This illustrates the indefiniteness of his formulas when applied to the problem of flood determination, in the form in which, from the writer's experience, this problem usually occurs.

Again, in the case of Tohickon Creek, Mr. Fuller apparently does not mean by his formula for the average maximum flood of that stream, $Q = Q$ (Ave.) $(1 + 0.76 \log. T)$, that we may expect a flood at least as great as, or in other words, equal to or greater than 6 300 cu. ft. per sec. once in 5 years, for his own analysis of the same data (Table 5, Part *c*) shows that we may expect a flood to equal or exceed 6 300 cu. ft. per sec. on an average only once in about 10 years, or one-half as often.

On reading the paper carefully, the writer is of the opinion that the author has failed to set forth clearly the meaning of his own deductions. The writer's understanding of the matter is as follows, referring to Table 5, Part *a*, for Tohickon Creek.

The average magnitude of maximum floods having average intervals of recurrence between 5 and 25 years is 1.53 times the mean flood, or 6 300 cu. ft. per sec.

**Proceedings*, Am. Soc. C. E., May, 1918.

Mr. Horton.

The average magnitude of floods having intervals of recurrence between 2.50 and 25 years is 1.29 times the mean flood, or 5 310 cu. ft. per sec., and so on.

The results of the author's general formula bear the same interpretation, except that it is probably approximately true, from the method of analysis used, that Q, in the formula, represents approximately the average volume of all floods having an average interval of recurrence greater than T, it being here assumed that the formula is correct for the particular stream in question.

What Mr. Fuller has really deduced is not the average magnitude of the floods having, for example, 25 years or 12.5 years average interval of occurrence. Statistically speaking, there can be only one magnitude of the maximum flood having for example 25 or 12.5 years average interval of recurrence. The appellation "average maximum flood" of a given interval of recurrence seems to be misleading and inaccurate. If we had a long enough record, and were to divide it up arbitrarily into 25-year periods, and were to take the average of the maximum floods of each period, we would get a quantity having some semblance to a maximum average flood of 25 years interval, but the writer fails to see any practical value in such a result. Furthermore, the result would obviously be very likely to be affected by the mode of dividing up the record, which condemns the method.

Take, for example, the 5-year Tohickon flood of 6 290 cu. ft. per sec. The author does not mean that we may expect a flood of just this magnitude on an average of once in 5 years. As a matter of fact, the probable average interval of recurrence of a flood of just this magnitude is very much greater than once in 5 years.

The writer cannot see that results in the form of the "average maximum flood" are of much practical use, but, if any one wants them, they are derived more easily and directly by the method shown in Table 5, Part *c*, than by the method used by the author.

In addition, it would seem that the method of Table 5, Part *c*, when properly applied, has several other decided advantages.

1.—It is simpler of application, requiring three columns instead of five.

2.—It gives directly the average interval of recurrence of a flood equal to or greater than a given magnitude. This is a factor of great importance, and has direct application in designing spillways, determining high navigable stages of waterways, etc.

3.—It enables the average interval of recurrence of a flood lying between any two given magnitudes to be readily determined.

For example, from Table 5, Part *c*, the average interval of Tohickon floods at least 1.21 times the mean, or 4 968 cu. ft. per sec., is five years. Their probability is, therefore, $\frac{1}{5} = \frac{5}{25}$.

Mr. Horton.

The average interval of floods of at least 1.45 times the mean, or 5 958 cu. ft. per sec., is 8.33 years. Their probability is, therefore, $\frac{1}{8.33} = \frac{3}{25}$. The probability of a flood between 4 968 and 5 958 cu. ft. per sec. is, therefore, $\frac{5}{25} - \frac{3}{25} = \frac{2}{25} = 0.080$, or the probable average interval of recurrence of a flood between 4 968 and 5 958 cu. ft. per sec., or of a flood having an average of about 5 460 cu. ft. per sec., is 12.33 years. Now, if Table 5, Part *a*, and the formulas deduced by the method there given, mean what the author says they do, would we not expect floods of this average magnitude to occur at intervals of about 3.57 years, instead of 12.33 years, as actual experience shows to be the case? This illustrates what seems to be a fatal error in the author's method of analysis.

It would appear that the relation between flood magnitude and frequency, when expressed in terms of either "average maximum flood" or "median flood," is not only very indefinite and difficult of comprehension, but is apt to be very misleading, if it is not indeed practically meaningless. It does not directly convey the information which the engineer usually most desires, for example: If a spillway has a capacity of 1 000 cu. ft. per sec., how often on an average will its capacity be exceeded?

Further, in Tables 4 and 5 for Tohickon Creek, the author has arbitrarily excluded from consideration all floods which did not exceed the average yearly one of 4 117 cu. ft. per sec. He has excluded thirteen floods and used eleven. Instead of following the rule "of making the best possible use of all the available information", he has made no direct use of considerably more than half of it. What the author was seeking was, it may be assumed, to find the law defining the relation between the magnitude of floods and their relative frequency of recurrence. If one were seeking to determine the law of velocity of falling bodies, and had 25 observations of the time required for different weights, varying from 10 to 60 lb., to fall through given heights, it would hardly be considered good scientific method to discard *a priori* all observations on weights of less than 35 lb.

Mr. Fuller's method of working with ratios (Table 5), instead of actual flood volumes, seems to be confusing and cumbersome. The data which the engineer has to start with are actual flood volumes; what he desires to determine, as a rule, as in designing a spillway, is a flood volume which will not be equalled or exceeded on an average oftener than once in a given interval, say, 100 years.

If we had two drainage basins, *A* and *B*, which were similar figures, with similar drainage systems, or "stream nets" as the German hydrologist calls them, and identical in geology, soil, topography, slope,

culture, and climate, but if A were larger than B, and if Q_A and Q_B were the true maximum 24-hour floods to be expected on these streams in an average interval of T years, then the difference between Q_A and Q_B would be the difference in flood-yielding capacity due to area alone. Mr. Horton.

In practice, however, it often happens that one area much larger than another does not yield a materially larger flood. If the data of such heterogeneous basins are plotted together in terms of area as abscissas, it appears to the writer that the results will be so discordant as to render the conclusions drawn therefrom of doubtful value.

Here we come squarely against the question of the physical, and not merely the statistical, aspects of the question. The latter only are covered by Mr. Fuller's discussion.

In the climate of the North Atlantic States local thunder storms nearly always produce maximum floods on very small areas, though only broad general cyclonic storms produce floods on the larger and medium large rivers, like the Hudson, the Susquehanna, and the Delaware. Now, thunder storms produce rains of great intensity but short duration. Broad cyclonic storms produce rains of low intensity but long duration, so that the relative flood intensity for different areas is not wholly determined by the relative times required for the water to reach the stream, or by the physiographic or cultural conditions, but partly by purely meteorological conditions.

The paper contains a valuable collection of flood data. It would have been easy to include the dates of the maximum floods, and these would be of use to engineers in comparing simultaneous flood intensities at different places. The writer cannot help feeling a sense of regret that so much labor has been expended in analysis of flood data along lines that do not seem to be either the most scientific or the most useful to engineers.

The ambition to place the results of one's investigations in the hands of the Profession at the earliest date is laudable, if indulged in with moderation. The writer's only excuse for withholding from publication the results of his own studies along similar lines for so long a time is that he thought it better to try the method out in practice first, rather than run the chance of punishing the Profession by the publication of that which might later prove to be premature.

The writer happens to have collected all the data contained in Table 13. Many of the floods there listed have subsequently been exceeded.*

CONCRETE BRIDGES: SOME IMPORTANT FEATURES IN THEIR DESIGN. Discussion.*

By Messrs. C. E. Gregory, Henry H. Quimby, A. C. Janni, Philip Aylett, and L. J. Mensch.

Mr Gregory.

C. E. Gregory, Assoc. M. Am. Soc. C. E.—The speaker was the Designing Engineer in charge of the design of bridges built by the Board of Water Supply, as referred to in this paper, and wishes to make a few statements to amplify the relation of the work as done by the Board of Water Supply to this paper, and to put others who were concerned in the design of these bridges in a right position in regard to it. The first point he desires to make is this:

The authors reach the conclusion that in practically all cases the three-hinged arch is more economical for long spans than the ordinary fixed-end arch. When designing the Traver Hollow Bridge, the speaker did not, and does not now, concur in such a conclusion. The three-hinged type was selected largely because of expected slight settlement in the foundations, rather than the economy of the type of bridge. The preliminary estimates indicated that a three-hinged arch would be more expensive than a fixed-end arch.

The economy of the divided pier is brought out by the authors, but the manner in which the design of the piers of the Rye Outlet Bridge was arrived at differed considerably from that described in the paper, although meeting the assumptions of the authors. The interesting and unusual feature of this bridge is that it is an arcade of five reinforced concrete arches supported on exceptionally high piers. It was found that the yielding of the top of a high pier of ordinary shape under the unbalanced live load arch thrust (the height of the highest pier in this bridge being a little more than 100 ft.) would be sufficient to

*Continued from December, 1918, *Proceedings*.

Mr. Gregory. create considerable stress in the arch without exceeding the usual limits of stress or creating tension in the pier. The design was made to limit the yielding of the piers to that which could be safely and economically provided for in the arches. The entire arcade was treated as a complete elastic structure, and determination was made of what proportion of the unbalanced thrust from a loaded arch would be carried by the adjacent pier and by other arches and piers of the arcade. The shape and size of pier adopted was found to be necessary from calculations made as just outlined.

This work was done under the speaker's supervision by Mr. George L. Bennett and Orrin L. Brodie, M. Am. Soc. C. E., who were at the time assigned to Mr. Smith's staff, but worked on this problem under the speaker's immediate direction.

Mr. Quimby. HENRY H. QUIMBY, M. AM. SOC. C. E.—Experience in the design of concrete arches confirms the opinion expressed by Mr. Gregory regarding the relative economy of fixed and hinged rings, and the justification for the use of hinges. Computations for comparison of designs in several cases have failed to show any saving in cost of a three-hinged type over a fixed type when the ratio of rise to span was fairly good. Hinges are justified only when the foundations are unsatisfactory, or in cases where the arch is very flat. In a flat arch the crown movement due to change in length of ring from temperature is greater than in a high-pitched one, and the temperature stress may thus become great enough to warrant the use of a hinge to avoid it. The arches shown in the paper, however, are not flat, but have a good rise.

The authors give estimated quantities of concrete required for the arch rings in the two designs shown, and represent the fixed type as requiring 90% more concrete than the hinged. This is hard to understand. A fixed ring should require only a little more than a hinged ring. The depth at the crown must be about the same for each because the horizontal thrust is about the same, and any theoretical eccentricity, due to unsymmetrical loading, in the fixed ring will probably be fully matched by the effect of friction of the hinge in the other case, for the inevitable deflection caused by the weight of the floor imposed after the closure of the arch will be likely to produce the effect of eccentric thrust. At the quarter points the hinged ring will need considerably more depth than the fixed ring, and it will be only at the springing line that the fixed ring will be deeper and require more concrete. As the cost of effective hinges is quite considerable, the net result is generally the reverse of that reported in the paper.

If it be said that the greater depth of the fixed ring design in the paper was made because of temperature stress, the reply is that temperature stress necessarily increases with the depth of the ring, and adding to the depth because of such stress is somewhat like piling a

load on a horse's back to enable him to pull a heavier wagon—the poor legs may be overtaxed. Mr. Quimby.

It would seem, therefore, that there must be something wrong either with the estimates or with one of the designs.

The stone hinges shown in the paper give the impression of being likely to develop friction if they work at all, and this will entail eccentricity of stress in the arch ring, to that extent detracting from the only advantage of the hinge.

The matter of appearance of an arch is important in many places, and the bulging at the quarter that is characteristic of the ordinary hinged ring is distinctly ungraceful and displeasing to the miscellaneous eye which cannot understand the reason for it, while the eye of the designer who knows that the point of greatest shear is the point of greatest single stress, desires to see the arch thickest at the spring where that stress is the greatest.

One very important consideration in a discussion of stress in a masonry arch is the method of construction, and it is generally far more vital than temperature fluctuations. The old-fashioned method of laying up an arch ring from the springing line to the crown, with the attendant progressive deformation of the centering and consequent cracking of the earlier portion of the ring practically reduces the working thickness of the ring to a fraction of that designed, and may be the real cause of some failures that have occurred. The proper way to avoid cracks or initial stresses in the arch ring due to settlement or compression of the centering during construction is to build the ring in voussoir blocks with narrow key spaces between them. Then when all the blocks are made, and the centering has, therefore, nearly its full load, after the blocks have seasoned and shrunk, cast the keys. Of course, if the arch is small enough to permit the casting of the full length of the ring in one day—say within 10 hours—the separation into blocks will not be needed, because the first portion cast will be still plastic enough when the ring is closed to adjust itself to the deformed centering. It is impracticable to eliminate initial stress wholly, for any of the dead load that is added subsequently to keying will cause some deformation of the ring and consequently initial stress somewhere; but this should never be enough to be serious.

The claim advanced in the paper that concrete will weather better than good sandstone, and almost if not quite as well as granite, is hardly to be expected from an experienced observer of concrete work. If the authors know of any formula that will produce concrete with such a desirable quality, they should give it to the Profession. It is a poor quality of building stone that will not hold its surface and its edges better than the best concrete. The statement in the paper sounds a little over-enthusiastic. The friends of concrete will promote its use more effectively by avoiding extravagant claims for it.

Mr. Quimby. Another point in the paper that seems not entirely clear is the claim of marked advantage in the I-shape of arch rib. The arch ring is a column—not a beam. If the curve be true and the line of thrust be central, there is absolutely no beam action. Of course, the width—horizontal thickness—of the rib, and its depth or vertical thickness, should both be theoretically adjusted to make a column that will fail by crushing rather than by buckling, and this will require some minimum width. As regards lateral buckling, any given width is as effective at the mid-depth as at the flanges, and, in any case, suitable transverse bracing should be provided. The method of estimating the saving due to the coring out of the concrete at the sides is hardly fair, because a very large part of the cost of such concrete is in the support of it, and any increase or decrease in quantity will be proper to be charged at only the cost of the material and placing. Besides, the extra cost of the additional form work necessary for the paneling will materially reduce the seeming economy in material.

Replying to the question of a member as to the observed actual range of temperature in concrete arches: Two bridges, constructed within the past 5 years, with electrical resistance thermometers embedded at the mid-line, show temperatures in the concrete ranging far less than is usually assumed. The depth of embedment in one case is 2 ft. 6 in. and in the other, 4 ft. 9 in. The former is a spandrel filled arch and the other is an open spandrel. The maximum range of temperature recorded thus far has been from 31° Fahr. in winter to 73° in summer, and measurements of change in elevation of crown made at the same times show a rise and fall computed to correspond to a change of temperature throughout the arch ring of 45° Fahr. between the extremes of cold and heat.

Mr. Janni. A. C. JANNI, M. AM. SOC. C. E.—The statement, among others, made concerning the quickness, simplicity, and certainty of the design for three-hinged arches, deserves careful investigation, and should not be accepted off-hand, or as a matter of course.

Therefore, it is not without interest to recall what both theory and experience teach with reference to the equilibrium of this particular kind of construction, and to ascertain to what extent a designer may trust his results.

If S and S_1 (Fig. 5) are the two contact surfaces of the left hinge of an arch, P being the tangent point, and PN the normal to the tangent, T, it is known that as long as the line of action of a force, F, acting on the hinge, is contained within the angle APD (this angle being twice the angle of friction, ϕ, for the material of which the hinge is made), the system will be in equilibrium, provided, of course, the force, F, is a compressive one with respect to the tangent, PT. Similar remarks may be made regarding the surfaces, S' and S_1', of the hinge at the key.

Mr. Janni.

Therefore, as long as the two components of a force, P, acting on the system, will keep within the two angles, APD and $BP'D$, the system itself will be in equilibrium, and the points, A and B, are to be regarded as the extreme limits of this equilibrium position.

In other words, the system will be always in equilibrium under the action of any force the line of action of which cuts the area $ACBD$.

The foregoing demonstration is very plain, but its foundation is rather indefinite; in fact, it is all based on the assumption that the angle, ϕ, is a known quantity, and, even if that is true, there are two solutions, according to the theory, that satisfy the conditions of equilibrium and, especially for an arch of large and flat span, give quite different results.

Concerning the friction laws, it can be said that, outside of those values of ϕ reported in all engineers' handbooks, which for every-day purposes are tolerably reliable, those laws are not well known at present.

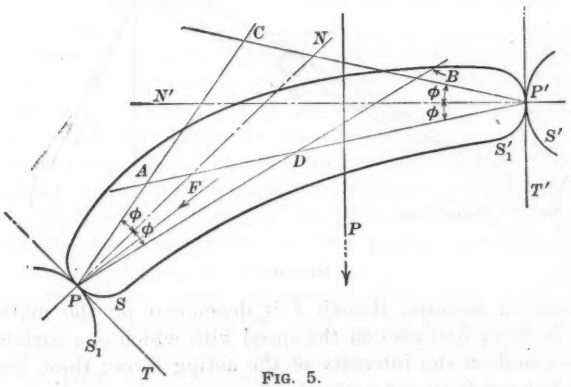

FIG. 5.

The history of the researches on friction is very brief. Amontos, in 1699, started for the first time a research on the friction of some machine of his, without, however, throwing any important light on the general matter.

In 1781, Coulomb took up the researches on this important problem and announced to the world his results, giving out laws on friction, as well as values of ϕ for different materials.

In 1785, Vince started his researches on the same question and rejected, as unreliable, Coulomb's laws and values of ϕ.

In 1829, G. Rennie, who made tests under about the same conditions as Coulomb, found more or less similar results.

Finally, in 1831, Morin presented before the "Académie des Sciences", in Paris, the results on his friction tests, and, though he

Mr. Janni.

confirmed Coulomb's fundamental laws, he found numerical values for ϕ which were very different. It is worthy of note that, though Morin made his tests on a larger scale than Coulomb, he did not go farther than a pressure of about 5.2 lb. per sq. in.

As far as the speaker knows, these are the only works on the subject which stand high on account of the illustrious names of their authors; unfortunately, they do not agree among themselves.

Modern investigations, however, without adding anything definite, have found that the friction law, as given by Morin,

$$R = fN$$

where: R = Resistance due to friction;
N = Normal component of the force acting on the body; and
f = A numerical coefficient depending on the materials in contact;

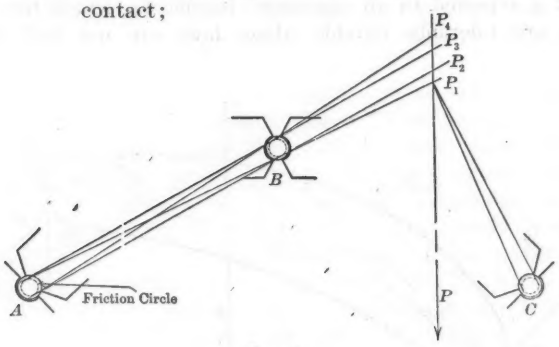

FIG. 6.

is not complete; because, though f is dependent on the materials in contact, it is dependent also on the speed with which one surface moves on the other and on the intensity of the acting force; these laws, however, have not yet been determined.

The only thing known at present is that the value of ϕ, at the start, is between 1.5 and 3 times its value during the movement, and this is quite a wide range when one considers the certainty of results.

Usually, the hinges are metallic, or, even in stone, they have a shape which might be regarded as a hinge; the problem then is solved, as is well known, in the following manner:

Let A (Fig. 6) be the left hinge of an arch; drawing the friction circle with the radius $r \sin. \phi$ (where r is the radius of the hinge and ϕ the angle of friction), it is known that all forces having lines of action which cut that circle will not move the hinge about its center, and all forces having lines of action tangent to that circle will be on the limit position of equilibrium, provided each of these forces has a tendency to compress the hinge against its groove.

Mr. Janni.

If B is the hinge at the crown, it is known that the four common tangents to the two friction circles are limit positions of equilibrium, therefore, according to graphic statics, the problem already admits of four solutions.

Taking now into consideration the third hinge, C, if P is a force acting on the system, and P_1, P_2, P_3, and P_4, are the points where the line of action of P cuts the four tangents, from each of those points can be drawn two tangents to the friction at C, which, according to the theory, will resolve the problem.

For the sake of brevity the hinge at B has been regarded as of the same kind as those at A and C.

Apart from the several solutions given by the theory on the equilibrium of this kind of construction, here, too, the indeterminations, resulting from friction, must be considered.

The friction circles can be drawn quite accurately for machinery, or when it is a question of pieces well prepared for laboratory tests, for which test after test has been made so that the whole question is somewhat settled.

Concerning the friction in bridge hinges actually in operation, however, on which the pressure is often so great as to wear off the material at the contract surfaces, it is to be said with regret that there has not been a single test known to the speaker.

It can be seen, therefore, that the quantity, $r \sin. \phi$, has not, by any means, a known and determined value; in fact, it is rather arbitrary. In other words, the set of four points, P_1, P_2, P_3, and P_4, can be substituted for another set of four points, provided they satisfy the requirements of graphic statics.

Although all the stated indeterminations (and there are others) do not prevent a designer from patching up some kind of design for a three-hinged arch, it is not possible to accept the statement concerning the reliability of such design.

The hinges, however, in a concrete or masonry arch can be used with advantage sometimes during the construction of the arches, when there is no steel reinforcement to take up the tension at the springing line and at the key, due to a possible excessive settlement of the centering; then, after the centering has been removed, the hinges should be concreted. Thus the arch behaves as a three-hinged arch, as far as the dead load is concerned, and as a rigid arch for the live load and temperature. In that instance the hinges, free from the enormous pressure of the dead load, can easily accompany any movement of it, being concreted afterward when their behavior begins to be extremely doubtful.

The granite railroad bridge at Morbegno, Italy, with 229.65 ft. span and 32.8 ft. rise, has been built in accordance with the foregoing method.

Mr. Janni.

In comparing concrete and stone bridges, the authors rightly state that one of the advantages of the former is that it is stronger and much more reliable, because of the absence of joints; therefore it is not clear why the paper is a special plea for the three-hinged arch, which has three joints, as compared with the rigid arch, which has none.

Concerning the statement that the trial design for a fixed-end arch takes several days for each analysis, it can be said that it takes no longer than the trial design for a three-hinged arch, and possibly less.

The stresses in the arch with fixed ends, due to dead load and temperature, can be calculated in a day's work easily.

A new method of designing an arch, based on the rather recent theory of the "Ellipse of Elasticity", is described in a paper by the speaker.* This is a purely graphical method and holds, irrespective of the geometrical form of the axis of the arch, irrespective also of the law of variation of the cross-section of the latter, and of the assumptions of loading. In other words, it is possible, by that method, to draw the lines of influence for moments, for any section of the arch, before the loads are applied on the arch, and, as a consequence, the most prejudicial hypothesis of loading for the chosen section is given at once, without any trial.

In that paper, in addition to the theoretical part, the speaker showed a practical application to an arch which he had designed and built by that method.

In contrast with the unreliability of the results in a design for a three-hinged arch, it is not without interest to relate that for a fixed-end reinforced concrete arch, built in France, having a span of 318 ft., the difference between the stresses calculated and the actual stresses reached a maximum of 14.7 per cent.

Every engineer fully appreciates the importance of these results, especially when he considers that, in steel bridges of the best design, that difference reaches 25%, and, when designed on the assumption that there is no friction at the joints, the difference may be more than 100 per cent.

The horizontal thrust, due to temperature changes, is directly proportional to the coefficient of expansion, to the change of temperature in degrees, to the modulus of elasticity of the material, and to the span (measured at the spring points of the geometrical axis of the arch); but it is inversely proportional to the inertia moment of the whole elastic arch with respect to the horizontal (if the arch has its spring points at the same level) passing through a certain point called the center of gravity of the elastic arch.

If, for the same span, arches with different rises are drawn, it can be seen that, although the factors directly proportional to the hori-

* *Journal*, Western Society of Engineers, May, 1913.

zontal thrust remain unchanged (the variation of the span of the geometrical axis may be disregarded), the moment of inertia of the arch increases rapidly with the increase of the rise of the arch; so that the effects of a change in temperature diminish in importance with the increase of the rise. Mr. Janni.

The shrinkage of the concrete due to setting and that due to the dead load are two important causes of stress to be taken care of, especially the former. If the arch is very flat and has a large span, the best and most economical way to take care of the shrinkage due to setting is by neutralizing its effects, as much as possible. A span of 170 ft. with 17 ft. rise, and two spans of 140 ft. with 14 ft. rise, designed by the speaker, have been built, breaking the arches into voussoirs each about 20 ft. long, and leaving between each two consecutive voussoirs a small voussoir, or key, of 2 ft. The voussoirs were cast first and the keys were not cast until the last concrete of the voussoirs was 10 days old, thus avoiding, for the 170-ft. span, for instance, important tensions on the intrados at the key and on the extrados at the springing line, especially during the winter, due to a shortening of $\frac{7}{8}$-in. of the geometrical axis of the arch, which otherwise would have taken place.

If, as the authors state, an average pressure of 12 000 lb. per sq. in. on the crown hinge of that arch was calculated, it must be inferred that the maximum pressure on the hinge was about 24 000 lb. per sq. in. at the theoretical point of contact with its groove, and it may be assumed that it was reduced to zero at each end of the groove.

The question then arises: At such a vital point of a bridge may the material be submitted to work at a rate which is never allowed for such material at other much less important points; and that without discussing the practical inadvisability of trusting on a $2\frac{1}{2}$-in. space the stability of such a comparatively enormous mass of material?

In dealing with such pressures, however, there is no longer any question of the possibility of assuming that at that point there is a hinge, ready to work; it is no more a matter of design, but of guesswork.

When a hinge of such small diameter is placed at the key, a malicious attempt to wreck the span could be successfully carried out.

Another kind of hinge—fortunately, very seldom used—is a ball-and-socket joint of cast steel consisting of a hemispherical protuberance fitting into a hemispherical cavity. Any horizontal displacement of the crown of the arch, for a structure of this kind, cannot be contemplated seriously; there is no reason for using such a hinge. In the construction of a three-hinged arch, the use of a ball-and-socket hinge means simply the addition of more friction at that joint.

Having an arch with only two ribs, and that arch hinged with the ball-and-socket type, then, at each joint cross-section there will be

Mr. Janni.

at least two hinges. Admitting, for the moment, that a horizontal displacement of the crown might take place, it will be admitted also, that it will be very small.

On account of the rigidity of connection between the two ribs, however, there is no possibility of a horizontal rotation of both hinges, even disregarding friction and admitting, of course, the elastic deformation of the whole system; but the effect of that displacement will be only to decrease the pressure on one hinge at the expense of the other.

However, as the use of a hinge of that kind shows that the designer assumed the possibility of a really tangible horizontal displacement of the key and the consequent horizontal rotation of the hinge, it is not without interest to ascertain what would happen to the arch if a horizontal rotation took place at the key, no matter how small it might be, provided, however, that it be a tangible quantity.

Assume that the hinge has a horizontal rotation of only 10′, and that the two hinges are 30 ft. apart; then, while one hinge presses in its socket during a rotation of 10′ (always disregarding friction), the other would be lifted out of its socket a distance of about 1 in. Although this will not happen, on account of the elastic deformation of the system, it is fair to admit that, at that joint, the horizontal thrust is zero (without speaking of the pressure concentrated on the rotating hinge).

What happens at the key, according to the designer's assumption, will happen also at the springing line, but the order will be reversed. Then the question arises: Did the designer calculate the stresses in his elastic system under such abnormal conditions of equilibrium? If he did, it is certain that he will never advocate the ease, speed, and certainty of a design for a three-hinged arch, especially with ball-and-socket joints; if he did not, then his enthusiasm for structures of this design is quite natural.

M. Mesnager, wisely concerned about the secondary stresses arising from the use of the hinges in arch bridges, and for which there is no way, at present, to determine their exact amount, thought that, a half-rigid joint "semi-articulation", the working behavior of which could be easily determined, would be preferable to the usual hinges.

For that purpose, several years ago, under his personal supervision, the Testing Laboratory of the "École des Ponts et Chaussées" started researches on a joint, Fig. 7, built in reinforced concrete according to his plans. Without going into details concerning his tests, it is enough to repeat one of his remarks:

"Le moment qui a été nécessaire pour fair fléchir la semi-articulation quand elle était noyée dans le béton, n'était pas négligeable."

Then he concluded by saying that it was possible, perhaps, to free the joint, *J*, from concrete and fill the remaining space with some kind of non-acid asphalt.

Evidently, a hinge of this kind, if developed properly, could not be expensive, and, at the same time, would eliminate the secondary stresses depending on friction, at least. Mr. Janni.

Concerning the saving of material by building the ribs of I-shaped section, it may be remarked that such a saving, in a general way, does not mean, necessarily, a saving of money. It would be rather absurd to think that a marble statue costs less than a block of the same material having the same external dimensions, only because the actual volume in the statue is less than that in the block. In addition, however, to all doubts expressed by other speakers concerning the cheapness of an I-shaped rib, as compared with the rectangular rib, another remark may be made: The three-hinged arch, on account of its lack of rigidity, requires a stronger system of stiffeners than that needed by a fixed-end arch, and the quantity of concrete in the stiffeners for the former must, necessarily, be greater than in those for the latter; therefore the statement advanced by the authors, that the quantity of concrete was the same in each case, cannot be accepted.

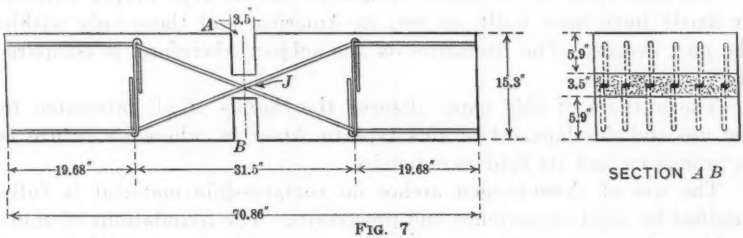

FIG. 7

In conclusion, it is to be noted that the statement concerning the complication of design for a fixed-end arch and the ease with which such an arch can be upset by a slight movement of one of its supports, is not altogether justified. This complication of design, so much complained of, is justified only if the designer expects to calculate the arch as simply as he can pick out, from the "Carnegie Handbook," the I-beams for a floor.

Concerning the latter remark (which was correct several years ago) it can be said that, by the theory of "virtual work" or, more elegantly and speedily, by the method of the "ellipse of elasticity", the designer can easily take care of such dreaded displacement of support, and even of a yielding of the soil on which the footings rest.

There is no doubt that the design for an arch is one of the most delicate problems of engineering; but, after all, it may be done without any great trouble if the designer is sufficiently familiar with his work.

The theories used are not monopolized by a few persons, but are quite accessible to any one of training and application. Fortunately for the designer, those theories cannot be reduced to "rule-of-thumb",

Mr. Janni. for several reasons. If an engineer, satisfied with what he was taught at school, does not keep in touch with the daily progress of science, he runs the risk, nowadays, of being behind the times. If, for instance, in designing an arch, he still assumes first that the arch is entirely loaded and then, that it is half loaded and half unloaded—still believing that, in this way, he ascertains the maximum stresses in that arch—he is flatly wrong; those assumptions were made several years ago, because there was then no means of ascertaining, conveniently, the most prejudicial hypothesis of loading; at present, however, that method of computing stresses is antiquated as well as inadequate.

Mr. Aylett. PHILIP AYLETT, ASSOC. M. AM. SOC. C. E. (by letter).—In America, the ribbed arch, especially the three-hinged type, has not received that recognition of its merits which it deserves. Its economy and advantages are better known and more highly appreciated in Europe, where it has been used extensively under almost all conditions of site and traffic, and in great variety of form and design.

Comparatively few concrete bridges of the rib type proper (hinged or fixed) have been built, as yet, in America, and these only within the past decade. The literature on the subject, therefore, is comparatively scant.

The authors of this paper deserve the thanks of all interested in the use and development of this type in America, where its future is so promising and its field so extensive.

The use of three-hinged arches on compressible material is fully justified by ample experience and precedents. The foundations of abutments and piers in such cases, however, demand more careful investigation, study, and design. A fixed or a two-hinged arch may also often be built with entire safety on compressible material, provided the foundations are properly designed and built, including the use of batter piles and other methods of taking up thrust. This also is justified by numerous structures under such conditions now extant, both in Europe and America.

The seeming economy of the rib of I-section, as compared with the rectangular, will not show so vividly in practice as on paper. This saving in concrete in the I-section will be largely, if not entirely, offset by the greater expense caused by the additional material and labor involved in making and placing the I-forms and depositing the concrete therein. Forms for such sections also necessitate the cutting up of the lumber into many short lengths, thus making much of the material unfit for other use. For instance, Fig. 8 shows an I-section form designed for the purpose of economizing in material and in the labor of making, placing, and dismantling it. This form is also capable of repeated use, as it is built in sections with this in view. Yet the

additional material and labor involved, in comparison with forms of rectangular section, is apparent at first glance. Mr. Aylett.

In addition, the I-section rib invites and makes possible injury and defects to the permanent structure from which the rectangular section is exempt. No one can foresee or forestall settlements in falsework or centering from timber shrinkage, "taking up", "biting", col-

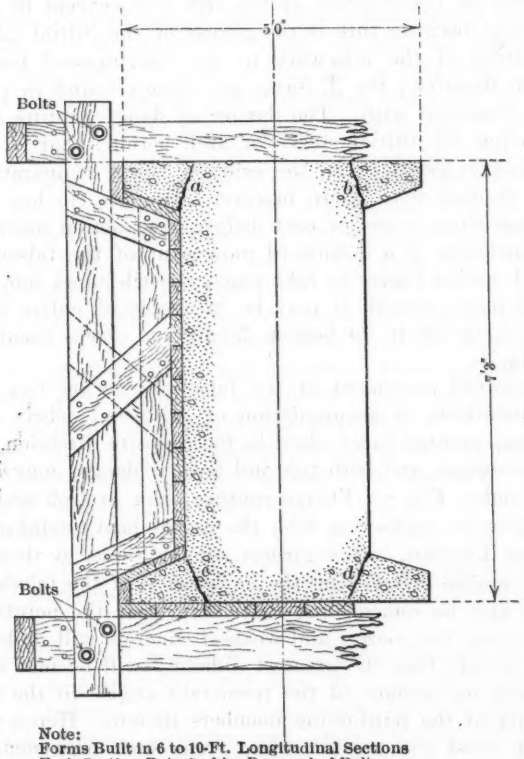

FIG. 8.

umnar shortening, foundation movements, expansion, contraction, etc., etc. Falsework or centering moves upward as well as downward on account of the unsymmetrical placing of the load, or in cases where the falsework becomes wet by rain or flood after being thoroughly dried out. A rectangular arch rib is capable of sustaining more settlement or upward movement of the falsework without injury than is possible with an I-section, because of the projecting flanges of the

Mr. Aylett.

latter. Settlements or movements of the falsework prior to the removal of the I-forms seriously endanger these concrete flanges, and will probably cause rupture at or near their junction with the body or web of the section, as at *a, b, c,* and *d,* of Fig. 8.

From a number of cases, it has been observed that the maximum movements of falsework (both up and down) occur during or immediately after the construction of the arch ribs (except in cases of accidents, etc.); because this is the period of the initial adaptation or accommodation of the falsework to its superimposed load. During this period, therefore, the I-forms are always found in position and cannot be dispensed with. The danger of flange rupture is most imminent during the initial stages of arch action; that is, when arch action begins to assert itself, the concrete being comparatively green.

Flange rupture may occur, however, after the rib has passed into the self-supporting stage, or even before arch action asserts itself at all. For instance, if a downward movement of the falsework occurs just as arch action begins to take place, the rib offers some resistance to the movement, though it may be incapable of entire self-support. The result is rupture in the bottom flanges and cracks opening upward, as at *d,* Fig. 8.

If an upward movement of the falsework occurs (on account of swelling, distortion, or accumulation of drift and débris against the forms), flange rupture takes place in the opposite direction, the cracks opening downward, and both top and bottom flanges may be affected, as at *a, b,* and *c,* Fig. 8. Flange rupture prior to arch action is most likely to occur in connection with the use of heavy reinforcing members, such as I-beams, lattice girders, etc., as these, by their own arch action, are capable of resisting the movements of the falsework.

It must also be remembered that at or near the points, *c* and *d,* in the I-section, the poorest and weakest concrete will undoubtedly be found. It is here that the greatest difficulty will be met in securing good concrete, on account of the re-entrant angles in the forms, and the proximity of the reinforcing members thereto. Hence the flanges which must resist the greater stress from such movements are less capable of doing so, on account of the quantity and quality of the material.

The likelihood of flange rupture (especially after arch action in the rib) may be decreased, more or less, by avoiding a rigid connection between the sides of the I-forms and the supporting timbers below. Thus, in Fig. 8, such a precaution may be provided by simply omitting (on both sides) the lower bolts shown in the verticals, and using stop-blocks instead. Slip-joints thus formed would permit the downward movement of the falsework without injury to the flanges, provided the arch had attained the stage of self-support.

Mr. Aylett.

Although the authors affirm that "the shape of the piers" is a "most important point in the design", they appear to overlook this and other important points relating to the design and construction of bridge piers, especially in flowing streams.

In the comparative estimates of the braced and solid types of piers, apparently, only the difference in concrete has been considered. The greater length of coffer-dam required by a pier of the braced type (with or without diaphragm or foundation offset) should be considered. In constructing coffer-dams in flowing streams, the important thing is usually time, for more risk is attached to coffer-dam building in flowing streams than in any other operation connected with ordinary bridge building, especially where there is "ice or logs of wood moving rapidly".

The many-sided dam of the braced type pier requires much maneuvering of the pile-driver in order to effect the frequent changes of direction. This involves change of anchorage, backing, going forward, etc., etc., all by men who are not sailors, and while breasting a current, and with risk of disaster by flood.

The solid rectangular pier requires less coffer-dam, less maneuvering of the pile-driver, less exposure to flood at the most critical time, and, consequently, much less time and expense. These are among the important points which should be considered in pier design and construction, and cannot be overlooked in any estimates.

There are, however, other features of the authors' braced pier which appear so serious as to preclude entirely this type from consideration in streams of the character mentioned.

The authors state:

"This type [braced] of pier is especially economical for a bridge in running water in which there is likely to be heavy blocks of ice or logs of wood moving rapidly."

Even prior to 1913 streams of this character throughout the country indicated, by ample evidence and signs, the imprudence of obstructing their flow. Railway officials and engineers, having interest in many streams over extended territory, were among the first to be impressed. Frequent and alarming flood records in numerous streams were observed. Bridge piers which had given many years of service, without trouble or expense, became the causes of claims and litigation on account of damage to adjoining lands by soil stripping and deposits of mud, silt, and débris, resulting from stream obstruction and current deflection.

It was observed that, usually, mud, silt, etc., were deposited in greatest abundance where the water first left the banks of running streams. This occurred in most cases immediately below bridge piers or other current deflectors.

Mr. Aylett.

Railway men and others who have borne the responsibility (night and day) of traffic and maintenance of way during flood periods, know the expense and risk attached to ordinary solid piers in running streams carrying ice and drift. The braced pier recommended by the authors for such locations would prove a veritable drift-trap and, viewing the matter broadly, appears to be a most obstructive and expensive type. Cut-waters, though valuable safeguards, especially against ice, do not prevent the lodgment of all logs and drift, even when solid piers of comparatively less widths are used.

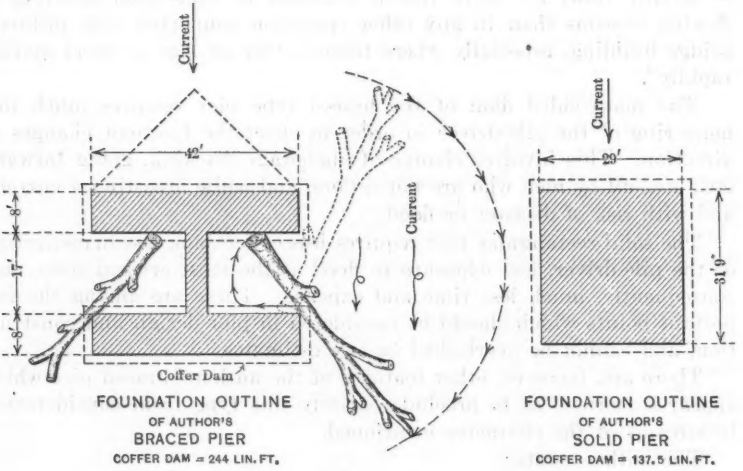

FIG. 9.

The authors' braced type of pier is exposed, not only to the accumulation of drift, etc., on its nose or up-stream end, as in solid piers, but will also catch and hold rigidly logs and drift in the space between the legs on both sides (Fig. 9). Drift thus trapped and held would not float and rise with the flood as it does with solid piers, and as it would be quickly submerged when caught, it would be almost impossible for an ordinary section gang, even with machinery, to dislodge it.

The buoyancy and enormous leverage of a mass of logs and drift, thus trapped, would exert a simultaneous lifting and wrenching action on the pier, increasing with the pressure of the rising flood on the growing mass held firmly before it.

Drift which collects at the noses of solid piers can always be removed by ice-hooks or pike-poles and floated away. Masses of drift cause deep scour around piers, and this would probably extend below the diaphragm, if its depth were only "down to where they [the pier-legs] enter the ground." If this should occur, heavy drift from both

sides might find its way under the diaphragm as well as the braces. It is difficult to reconcile the obstructive braced pier recommended by the authors with the nation-wide conservation movement of to-day, especially in the face of the experience of the West and Middle West in 1913, with its lessons so clearly, impressively, and profoundly taught. Mr. Aylett.

Amid the losses of lives and property, the bridge engineer's lesson stood out above all others—unmistakable and specific:

It was: Conservancy of Rivers by

(*a*) Avoiding unduly wide and obstructive piers;

(*b*) Reduction in number of piers by increase of span lengths;

(*c*) Increasing floor-level elevations.

These would facilitate the discharge and consequently help to lower the flood level. By so doing, other lives and property may be saved, and the sacrifices in the West and Middle West will not have been in vain.

L. J. MENSCH, M. AM. SOC. C. E. (by letter).—The statement of the authors that three-hinged arches contain only about half as much masonry as properly designed fixed arches is only true for bridges of very small rise, and the writer would be interested to see the calculations for the bridges shown in Fig. 3, as his own tables do not show such a difference. The fact is that the thrust in both types is practically the same. The bending moment caused by a concentrated load in a three-hinged arch is greatest when the load is 0.211 l from the abutment, and its value is about $P \times \frac{l}{10}$; in a fixed arch a concentrated load produces the greatest bending moment when placed 0.3 l from the abutment, and its value is about $P \times \frac{l}{16}$. Mr. Mensch.

It is customary to calculate a bridge for a uniform load, w, placed at its half span. The greatest bending produced in a three-hinged arch occurs at the quarter span, and amounts to $\frac{w \times l^2}{64}$; in a fixed arch it occurs at the point 0.3 l from the abutment, and amounts to $\frac{w\,l^2}{120}$; at the same time the moment at the abutment is $\frac{w\,l^2}{64}$.

There is nothing to justify the statement that there is a considerable saving in materials in a three-hinged arch over a fixed arch, unless the temperature stresses and the stresses due to the shortening of the arch and the shrinkage of the concrete play an important rôle, which is only the case in arches of comparatively small rise and large depth. Professor Howe, in his treatise on arches, showed that the thrust from a change of temperature in a parabolic arch of constant $\frac{d\,s}{I}$ may be found by the formula, $\frac{45}{4}\,\frac{E\,I\,c\,t}{f^2}$, when E = the modulus

Mr. Mensch.

of elasticity, I = the moment of inertia of the crown section, c = coefficient of expansion, t = change of temperature, in degrees Fahrenheit, and f = rise of arch; and that its point of application should be assumed at $\frac{1}{3}\,f$ below the crown. The writer finds that in a parabolic arch, as usually designed, the thickness of the arch increasing at the abutment to about $1\frac{1}{2}$ to 2 times the crown thickness, the thrust may be found by the formula, $24\,\frac{E\,I\,c\,t}{f^2}$, and its point of application may be assumed to be $\frac{7}{30}\,f$ below the crown. Let $E = 2\,000\,000$, $t = 50°$, $c = 0.0000055$, or $E\,c\,t = 550$.

From a change of temperature, the bending moment is found to be,

at the crown, $$\frac{24\,I}{f^2} \times 550 \times \frac{7}{30}\,f = 3\,080\,\frac{I}{f};$$

at the abutment, $$\frac{24\,I}{f^2} \times 550 \times \frac{23}{30}\,f = 10\,120\,\frac{I}{f}.$$

For a width of 1 ft. of the arch ring, $I = \frac{12\,d^3}{12}$, when d = the thickness at the crown; the moment at the crown $= 3\,080\,\frac{d^3}{f}$, and the moment at the abutment $= 10\,120\,\frac{d^3}{f}$.

If we consider that the moment of resistance of the crown section for a width of 12 in. (neglecting the reinforcement) $= \frac{12 \times d^2}{6} = 2\,d^2$, and that the moment of resistance at the abutment, when the thickness is twice the crown section $= \frac{12 \times 4d^2}{6} = 8d^2$, we can obtain for the stresses in the extreme fibers caused by the change of temperature, by dividing the moments by the section modulus, the simple expressions, $1\,540\,\frac{d}{f}$ for the crown section, and $1\,265\,\frac{d}{f}$ at the abutment, whatever the span of the arch.

The writer will endeavor to compare the two bridges shown in Fig. 3, as far as the few measurements given will allow. He will assume that the thrust per linear foot may be found by the formula, $\frac{850 \times 128.5^2}{8 \times 25} = 70\,000$ lb. The live load of 100 lb. per sq. ft. distributed over a width of 29 ft. will amount to $\frac{100 \times 29}{17} = 170$ lb. if

distributed over the two arch rings 17 ft. wide; and the bending moment in a three-hinged arch at the quarter span Mr. Mensch.

$$= \frac{170 \times 128.5^2}{64} = 44\,000 \text{ ft-lb. per lin. ft.}$$

The crown thickness of the arch is 22 in., and assuming that the thickness at the quarter point is 33 in., the stresses at the quarter point may be found as follows:

The compressive stress $= \frac{70\,000}{33 \times 12} = 177$ lb. per sq. in.

The stresses in the extreme fibers from the bending moment

$$= \frac{44\,000 \times 12}{12 \frac{33 \times 33}{6}} = 242 \text{ lb.}$$

or a maximum compressive stress of $177 + 242 = 419$ lb.
and a maximum tension of $242 - 177 = 65$ lb.

The average thickness of the arch is $22 + \frac{2}{3} \times 11 = 29.33$ in.

In a fixed arch it will be necessary to assume a greater thickness of the arch at the crown, on account of the temperature stresses; therefore, the thickness at the crown will be assumed to be 28 in. and that at the abutment, 56 in. The maximum bending moment caused by a uniform load, w, per square foot at the crown is about $\frac{w \times l^2}{320}$, and the compressive stress from the thrust $= \frac{70\,000}{12 \times 28} = 208$ lb. per sq. in.; the stresses in the extreme fibers, from the uniform load, $= \frac{170 \times 128.5^2}{320}$, divided by $\frac{12 \times 28^2}{6} = 56$ lb. per sq. in.

As shown before, the temperature stress in the extreme fibers $= 1\,540 \frac{d}{f} = 144$ lb. per sq. in., or a maximum compressive stress of $208 + 56 + 144 = 408$ lb. and a minimum compressive stress of $208 - 200 = 8$ lb. per sq. in. At the abutment, the thrust is $70\,000 \times 1.28 = 89\,500$ lb. and the compressive stress $= \frac{89\,500}{12 \times 56} = 133$ lb. The maximum bending moment from a uniform load

$$= \frac{170 \times 128.5^2}{64} = 44\,000 \text{ ft-lb.}$$

The section modulus at the abutment $= \frac{12 \times 56^2}{6} = 6\,280$ in.^{3}, and the stresses in the extreme fibers $= \frac{44\,000 \times 12}{6\,280} = 84$ lb.

Mr. Mensch.

The temperature stresses $= 1\,265\,\frac{d}{f} = 118$ lb., or the maximum compressive stress $= 133 + 84 + 118 = 335$ lb. per sq. in., and the maximum tensile stress $= 202 - 133 = 69$ lb. per sq. in. The average thickness of the arch $= 28 + \left(\frac{1}{3} \times 28\right) = 37.33$ in.

The stresses from the shortening of the arches will modify the results only very slightly in this case. Although both bridges have about the same stresses, the average quantity of concrete is only 27% greater in the fixed than in the three-hinged arch. Or, assuming that 200 cu. yd. for the three-hinged arch is correct, the saving amounts to only 54 cu. yd., or $675, which is more than counterbalanced by the cost of steel hinges.

The authors state that the slightest movement of the abutments will develop cracks in the arches. This is not the case. A temperature drop of 50° is equivalent to a movement of both abutments of $\frac{1}{3\,640}$ of the span, or, in this case, 0.42 in., and it is a poorly designed abutment in which this movement will be seen. Such a movement would increase the stresses at the crown to $408 + 144 = 552$ lb. in compression and $144 - 8 = 136$ lb. in tension, and at the abutment to $335 + 118 = 453$ lb. in compression and $69 + 118 = 187$ lb. in tension. It is known that ordinary slabs do not crack under stresses less than 300 lb. per sq. in.; hence the factor of safety against the first crack is still ample.

It is true, however, that the temperature stresses and those due to the shortening of the arch would be three or four times as great in the same arch with a rise of only one-tenth of the span, and the advantage of the three-hinged arch in such a case is unquestioned.

In a three-hinged arch, great stresses may be caused by the unequal settlement of the staging, and it has often happened that the hinges have been thrown out of line and out of center, and have had to be dug out and replaced. The failure of a large bridge was due to this cause. This is the main reason that fixed arches are preferred by experienced engineers to the three-hinged type.

It must also be mentioned that three-hinged arches settle considerably more than fixed arches after the centering is struck, and also cause more vibration under moving loads.

In three-hinged arches, the use of deep ribs is a decided saving, which is not the case in all fixed arches. The writer has advocated* the use of I-sections for spans of more than 300 ft., and for spans of from 200 to 300 ft. he advocates T-sections.

The rule given by the authors for finding the center line for a three-hinged arch can be simplified by assuming the entire arch to be loaded by one-half of the uniform load per square foot. This, according to the elastic theory, gives the most favorable line of pressure.

THE EFFECT OF SATURATION ON THE STRENGTH OF CONCRETE.

Discussion.*

By Henry H. Quimby, M. Am. Soc. C. E.

Mr. Quimby.

Henry H. Quimby, M. Am. Soc. C. E.—Mr. Worcester's discussion brings up recollections of some early experience with concrete. Certain 6-in. test cubes made by an inspector in the field yielded very unsatisfactory results when crushed, breaking as low as 500 lb. per sq. in. The cement, which was a standard Portland brand, and the sand, which was New Jersey bank sand, were suspected and retested, but were found to be normal. The concrete was friable—the edges easily rubbed off with the thumb—and it was very absorbent. Tensile test briquettes of the mortar—1 to 3—made at the same time as the cubes, tested as low as 39 lb. at 7 days. Some broken pieces partly immersed in water to observe their absorption were noticed after a few days to have considerably higher tenacity. Similar experiences on other work later, and also some experiments, made it clear that premature setting and drying out prevents concrete from properly ripening.

The trouble appears in hot weather when all the materials have been heated by exposure to the sun, and perhaps when, in addition, a quick-setting cement is used. When concrete is found to be deficient in strength because of premature drying out, continued saturation with water will increase its strength, but will probably not raise it to the normal point unless the saturation be continued for a very long time.

It is evident that concrete wants its moisture and time together.

In order to secure uniform conditions of treatment of test cubes, the rule has been adopted for all inspectors to bury each cube in moist earth as soon as it is removed from the mould, and keep it there until it is sent in to the testing laboratory to be crushed.

MEASUREMENT OF THE FLOW OF STREAMS BY APPROVED FORMS OF WEIRS WITH NEW FORMULAS AND DIAGRAMS.

Discussion.*

By Messrs. L. M. Winsor, H. W. King, and Robert E. Horton.

Mr. Winsor.

L. M. Winsor, Esq.† (by letter).—One of the most crying needs to-day of the entire irrigated West is careful attention to accurate methods of measuring the flow of streams and to the proper distribution of this flow. Through the continual development of larger areas under irrigation, water has become or is rapidly becoming much more valuable than the land it covers. Water users are no longer satisfied with the loose methods of division which were put into practice during the early years of irrigation development. Each season brings new demands for an accurate system of measurement and distribution. For this reason it is high time that the Engineering Profession perfect some accurate, economical, and at the same time simple, device to meet this demand.

The weir in its various forms has been accepted as the device best suited to the needs of the irrigator. Before adopting it as a standard, however, it would seem advisable to make a more careful study of its use, under actual field conditions, than has ever been made. Most of the observations thus far have been conducted under conditions quite foreign to those which are met in the operation of a canal system. The early experimenters used, in the main, larger streams than the ordinary irrigation stream requiring measurements, and the recent experiments were conducted under laboratory conditions which are seldom applicable to the ordinary irrigation stream.

* Continued from December, 1913, *Proceedings*.

† Asst. Irrig. Engr., Office of Experiment Stations, U. S. Dept. of Agriculture, Logan, Utah.

Mr. Winsor. The work being done at the new laboratory at Fort Collins, Colo., under the immediate direction of Professor C. M. Cone, of the Division of Irrigation Investigations, U. S. Department of Agriculture, will without question throw a great deal of new light on the matter of water measurement, and is no doubt the most important work of its kind going on to-day. This laboratory is equipped to make measurements under practical conditions, and the results there obtained will be of untold value to the irrigators of the West, and to the irrigation engineer.

The sharp-crested rectangular weir without end contractions, recommended in the paper, is without doubt one of the best forms, if not the best, now in use, where it can be put in place properly. It is not, however, as easy to erect for ordinary use as is the weir with end contractions. The latter can be placed directly across the channel without the trouble or expense of constructing a channel of approach, the only requisite being the enlargement of the up-stream portion of the stream bed to a sufficient area. In practice, the weir, or any other device, must be adopted by degrees. Farmers or canal operators object at first to any device which is expensive; therefore it is well to give due consideration to one which will give results approaching accuracy, and at the same time admit of construction. When canal operators are educated to the proper point, the most accurate of the various devices may be recommended, even if expensive.

In any case, if the suppressed weir is to be used, it is very important that the area of the up-stream channel be enlarged considerably in order to reduce the velocity above the approach to the weir to such an extent that it will not affect the flow.

The point made by the author that the velocity over a suppressed weir is greater than that over a contracted one is very important when applied to most western streams, which carry a great deal of sediment. This deposit of sediment above the weir is one of the main factors in prohibiting its use under irrigation conditions.

In the writer's opinion, the discussion of the various forms of broad-crested weirs, as applied to the present needs of the country, is less important than the portion devoted to the sharp-crested weir, and particularly to the first three plates or diagrams. Great credit is due the author for his originality in working out this system, and particularly for his clear and concise comparisons between the various experiments.

Mr. King. H. W. KING, M. AM. SOC. C. E. (by letter).—The weir experiments of Francis, Fteley and Stearns, and Bazin have been examined so minutely, and have been grouped and studied so carefully and thoroughly by so many able hydraulicians that it would hardly seem possible to evolve anything really new from them. The author, however, by his method of combining into working diagrams the results

of these experiments and the more recent ones of the Cornell and University of Utah Hydraulic Laboratories, has done much to simplify the use of this mass of data. The contribution is a most valuable one, because of the new methods of analysis developed, as well as the practical value of the results obtained. Mr. King.

Inasmuch as the author did not endeavor to derive a general formula of discharge, he was able to obtain several formulas for each series of observations which fit very closely each value given. These exact formulas were in turn used in deriving the quantities used in the diagrams. It is evident that the author is consistent in his methods of constructing these diagrams, and they represent accurately the results obtained from the experiments. There can be no doubt that quantities can be picked off the diagrams with as great accuracy as is justified by the results of the original experiments, and, doubtless, they furnish the most ready and reliable means yet provided for solving problems of the type to which they apply.

This paper, however, should be considered as a very comprehensive study of one phase of the subject of weirs rather than a general analysis. The author takes up the single case of a weir in a channel of rectangular cross-section in which the length of the weir is equal to the width of the channel. This is the condition under which many, if not most, of the weir experiments above referred to were made. In constructing a weir for the measurement of water, it frequently happens that these requirements may be fulfilled. It is not true, however, that this may be done in all cases. In many cases the engineer wishes to measure the flow of water by the weir method in a canal of trapezoidal section or a stream of irregular section. There is, moreover, a question as to whether it will be practicable under all conditions to require the measurement of irrigation waters by suppressed weirs in rectangular channels, as the author suggests. These ideal conditions should be obtained when practicable, but there seems to be no good reason for limiting the use of the weir to this one case.

Occasions will continually arise when it will be desirable to construct weirs across other than rectangular channels, and there will consequently continue to be need for an accurate solution of these problems. It also appears that we are not yet ready to dispense with the weir with end contractions, and, therefore, there is still need for a means of determining the discharge over such weirs. It is doubtless true that, for maximum accuracy, with our present limited data and knowledge regarding the flow over weirs, the channel of rectangular section and suppressed weir should be used where practicable. This, however, is due to the fact that the experimental data thus far obtained apply more particularly to weirs of this type, and not

Mr. King. because those constructed under other conditions may not be possible of as exact solution.

In order that a method of solution of weir problems may be of general application, it must provide for a channel of approach of any cross-section. It should also, with proper modifications, include the weir with end contractions. It would appear, therefore, that the foundation of the method of solution must apply to the weir discharging from the theoretically quiet pond. The coefficient of discharge under such conditions is well known to be very close to a constant quantity within the range of head covered by our present experimental knowledge. The deviation of this coefficient from a constant, therefore, is due almost entirely to effects of velocity of approach. The present weir formulas, with the exception of Bazin's, use this general method of solution; that is, they determine the discharge from a still pond and correct the observed head, so as to include the increased discharge due to velocity of approach. That these formulas do not give results of sufficient accuracy is unquestioned. The trouble, however, does not lie in erroneous theory or assumptions, but in being based on insufficient if not partly unreliable experimental data.

There still remains to the Engineering Profession the problem of providing a satisfactory general method of solution for all weir problems. Such a method of solution must be based largely on new data, which should cover a wider range than those existing, and be of unquestioned accuracy. New experiments are needed to give more definite knowledge of the discharge over weirs without velocity of approach, which will replace the assortment of formulas in use at present. There is even greater need of complete data which will give a clear understanding of the laws governing the flow of water, the distribution of velocities in the channel of approach, and the effect of these laws on the discharge over weirs. At present, adequate facilities for such experiments are not available, but it is to be hoped that a means will soon be provided for obtaining these much needed data. With them a ready means should be provided for solving all weir problems within the required limits of accuracy.

Mr. Horton. ROBERT E. HORTON, M. AM. SOC. C. E. (by letter).—The writer regrets that he has been unable to find time to give this paper the careful perusal it undoubtedly deserves.

Heretofore, a thin-edged weir, constructed substantially in accordance with the rules laid down by the late James B. Francis, Past-President, Am. Soc. C. E., has commonly been designated a "standard weir", and has often been accepted by the Courts as a correct method of measuring water, whether or not it was so in fact. The writer agrees with Mr. Lyman to the extent that a suppressed weir is an equally good "standard", but questions the propriety of legalizing this

or any other form of weir as a "standard". It seems to the writer that there are now a considerable number of forms of weirs, all sufficiently well calibrated to serve as excellent standards in particular cases, no one of which is the best standard for all cases. Mr. Horton.

The hydraulics of weir discharge is by no means as simple a matter as it may appear to a neophyte. A good engineer can get good results with good weirs of various forms. The writer does not hesitate to say that he has seen "Francis Standard" weirs abused—and the results sworn to in Court—in a startling manner. Such abuses are usually coupled with the opinion, tacit at least, that as the weir is denominated "standard", it is consequently fool-proof, and the element of personal equation is eliminated.

Great injury has been done by writers of textbooks on hydraulics by placing undue stress on the merits of so-called standard weirs and orifices, especially the latter, as compared with other forms. Almost any kind of a round-edged orifice, with a reasonable edge radius, is subject to less variation in coefficient in practice, and is less likely to be obstructed or change its form, than a thin-edged orifice. The same is true to some extent for weirs. It is also true in both cases that the round-edged form discharges more water for an opening of a given size then the thin-edged form. This is a matter of some importance, in the case of orifices, in measuring the supply of water-wheels through flume or bulkhead openings where water is sold or leased in square inches or other units. It is a matter of great importance in designing flood spillways for dams, because, with a given length, the round-crested spillway, having a larger coefficient, will discharge a flood with a less depth of back-water than a broad flat or a thin-edged weir. The floods in the spring of 1913 demonstrated pretty clearly that spillways of dams form the best practicable method of measuring the maximum flood discharge of rivers, and for that purpose, ogee or round-crested weir sections are the best practicable standard.

Mr. Lyman describes various base formulas which, with suitable coefficients, have been used for calculating the discharge over weirs of various forms. In the original deduction of the U. S. Geological Survey experiments of 1903*, the writer chose the theoretical formula, which had also been adopted as a base formula by Francis for thin-edged weirs:

$$Q = C\,L\,H^{\frac{3}{2}}$$

The reasons were as follows:

(1) The results in this form for irregular sections are directly comparable with the discharge of a thin-edged weir, when the latter is calculated by the formula then in most common use.

*As described in Water Supply Papers Nos. 150 and 200. The table of multipliers appearing at the end of these papers was inserted after the paper left the writer's hands, and without his sanction.

Mr. Horton.

(2) The coefficients for many forms of weirs of irregular section are not continuous functions of the head, so that the full history of the discharge under a wide range of heads cannot be represented by any single formula with a constant coefficient.*

(3) If, as is true in many, but by no means all, cases, a variable coefficient must be used in formulas for such weirs, then it seems better to throw all the variation into the coefficient and make the computation as simple as possible by using the $\frac{3}{2}$ power of the head, instead of causing the head to vary according to some other fractional or decimal power, which would require the use of logarithms, logarithmic paper, or a logarithmic slide-rule for practical computations.

Judgment based on experience is one of the best checks on computations, and is often a valuable criterion as to the reliability of experimental results, and, for this reason, the writer prefers to compute experimental results in the first instance in some manner that will make such results commensurate with some established scale or "yard-stick", as the Francis formula for weirs, or the Chezy-Kutter formula for channels.

If the results appear reasonable, they may afterward be applied to any formula desired. Francis applied an exponential formula to the Merrimac River Dam.

The writer early recognized the value of the exponential formula for certain forms of weirs, and applied it where it seemed to fit. Later, Mr. Philip Parker, using the writer's computation of the Bazin, U. S. Deep Waterways, and U. S. Geological Survey experiments, deduced exponential formulas for a large number of weirs.†

The writer is not in sympathy with the practice adopted by some, of working out a table of multipliers to be applied to the calculated discharge over a thin-edged weir to obtain the discharge over an irregular crest-section. First, the discharge over the weir in question might as well be calculated in the first instance, thus saving a deal of computation, with chances for error; second, for a given head and cross-section, the velocity of approach correction varies with the discharge coefficient, so that for two weirs, one thin-edged and the other of irregular section, with the same measured head, but with different sections of approach, the use of multipliers becomes confusing and may be a source of error.

The use of either the Francis base formula or the exponential formula, both with varying coefficients where necessary, seems to the

* The presence of *points d'arret*, cusps, etc., in weir coefficient curves is shown very clearly in some of Bazin's experiments. See the writer's discussion of the paper by the late George W. Rafter, M. Am. Soc. C. E., entitled "On the Flow of Water Over Dams". *Transactions*, Am. Soc. C. E., Vol. XLIV, p. 345.

† A few of Mr. Parker's formulas appear in his recent work "The Control of Water."

writer better practice, for cases where there is no abrupt change in form of nappe, as when the water breaks free from a flat crest and assumes the thin-edge weir form, the exponential form of expression probably gives in many cases the simplest and most complete history of the discharge. Mr. Horton.

In conclusion the writer is prompted to remark, regretfully, as regards hydraulic science, "Of the making of many formulas there is no end."

TOPOGRAPHICAL SURVEYS MADE BY THE AMERICAN SECTION OF THE INTERNATIONAL BOUNDARY COMMISSION UNITED STATES AND MEXICO.

Discussion.*

By N. T. Blackburn, Assoc. M. Am. Soc. C. E.

Mr. Blackburn.

N. T. Blackburn, Assoc. M. Am. Soc. C. E. (by letter).—The writer was introduced to the practical side of the stadia method of surveying immediately after graduation from college, and has had a good deal of experience in its use along the coast of Texas, under the U. S. Engineer Office. Its adaptability and flexibility are so great that he has used it almost entirely, except for hydrographic surveys which take in large areas some distance from shore. Where two transits or sextants are not available for locating lines of soundings by intersection, and the lines do not run too far out from shore, a very good survey can be made by locating points on the lines of soundings with a stadia rod held in the sounding boat.

The writer agrees with the author as to the use of fixed stadia wires and the disregard of the $f + c$ factor. Where carefully measured base lines are run by this method, taking short distances, when the atmospheric conditions are favorable, and with great care in reading the rod, its use may be advisable. For ordinary work the $f + c$ factor is certainly a useless refinement, particularly on side shots. The writer has never attempted to read the rod closer than the nearest 5 ft. on side shots of any length, and he has never been able to guarantee that his side shots in open country, in the middle of the day, for distances of more than 1 500 ft., were within 15 ft. of the correct distance, on account of the trembling of the air. With ideal

* Continued from December, 1913, *Proceedings*.

Mr. Blackburn.

weather conditions—a cool, cloudy day with no wind, or very light wind—and short shots, it may be possible to read the rod close enough to allow a correction for $f + c$; but the writer's experience has been that it is generally impossible even to graduate a rod to fit the instrument exactly the same at two different times in the day.

On his first work the writer used the ordinary diamond diagram for the stadia rods, Fig. 2. This marking is plain and easily read except that in the hot sun in open country and at distances of 1 000 ft. or more, the red triangles tend to blur, and the dividing line is hard to distinguish. Moreover, any rod which has the same diagram for each 1-ft. interval is confusing to read. The red figures, however, are an advantage in woods or brush, as they show up in contrast to the foliage and undergrowth. A better form of marking is shown by Fig. 3. This was given to the writer by a member of this Society who was connected with the U. S. Reclamation Service at one time, and is understood to have been used by that organization. It will be noted that only every fourth foot is graduated to tenths. One stadia wire is set on a dividing line between foot marks so that the other wire falls within the divided block. Distances can be thus read more rapidly, particularly for long shots, as the length subtended between stadia wires can be read in 400-ft. blocks.

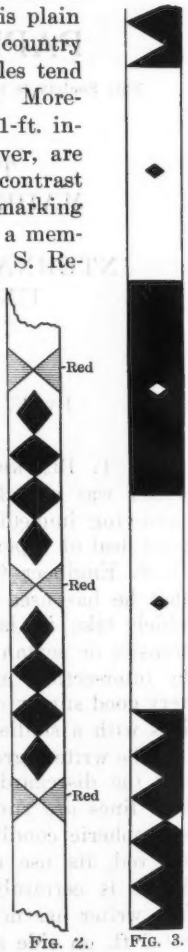

FIG. 2. FIG. 3.

A rib on the back of a rod is useful to prevent warping and to furnish a handle by which to hold it, but it adds to its weight and complicates its use as a line rod when taking azimuth. It has been the writer's experience that stadia rods warp badly unless carefully watched.

The author's tables showing errors of closure for stadia traverses are interesting and instructive. On a survey of Buffalo Bayou, Texas, a base line was run along each bank by transit and stadia, and the two lines were tied across at intervals of from 1 to 3 miles, thus forming a series of closed traverses from which the errors of closure could be computed. About six of these closures were thus made, and it was found that the error varied from 1 in 155 to 1 in 2 200. The distances on the 1 in 155 traverse were afterward chained and the error reduced to 1 in 1 930. The stadia work was done very carefully, and all distances were read forward and back, but no $f + c$ correction was made.

Mr. Blackburn.

In keeping notes the writer has always numbered consecutively his stadia hubs, and also all side shots from each hub. Then any side shot is located by a double number, first, that of the stadia hub from which it was taken, and then that of the side shot, thus: 15-1, 15-2, etc. A page of notes would appear as shown by Table 24. True south is taken as zero and true north would then be 180 degrees.

On the right page is made a rough sketch of the area surveyed, and the side shots are spotted thereon with their number placed alongside. A note is also made, on the same line as the notes, as to the object on which the side shot was taken. This method has always been clear to the draftsman. As a usual thing, it is better for each man to plot his own work, but this is not always possible, particularly if it is to be plotted as fast as taken. Where the rodman remains always some distance from the instrumentman, and is able to sketch fairly well, it is usually a good practice to furnish him with a book in which to sketch the topography and locate the points on which he has held the rod.

TABLE 24.

At.	On.	Distance, in feet.	Azimuth.	Magnetic bearing.	Vertical angle.	Elevation.
15	14	563	12° 20′	S. 4° 30′ W.	.....	.....
(H I. = 15.4)	16	750	220° 49′	N. 32°-50′ E.	.....	.....
.....	1	530	270° 50′	.....	5° 10′	.....
.....	2	650	155° 13′	.....	.....	.....
16	15	750	40° 49′	S. 32° 50′ W.	.....	.....

.....	1	220	192° 00′	.....	.....	.....

The writer has always used with success the method of observation on Polaris for azimuth given in Johnson's "Surveying."* However, it is plausible that the heat of the light used to read the verniers might affect the instrument, and he is glad to know of this.

During the winter of 1911-12 the writer organized and supervised a topographical survey of the Guadalupe River, Texas, on which methods similar to those described by the author were used, although not so accurately in some particulars. This survey extended over about 38 miles of the river, from a point about 14 miles above the mouth to the Town of Victoria (Mile 52), and covered not only the bed and

* Page 558 *et seq.*, 15th Edition.

Mr. Blackburn.

banks of the river, but an area about ½ mile back on each side. All distances were measured by stadia. A base line was run along the bank of the river, crossing from one side to the other wherever necessary to get the most open country. On this base a double-rodded line of levels was run very carefully. This base line then formed the horizontal and vertical control for the entire survey. The meanders of the river and all topography between the water's edge and the top of the bank were taken directly from this line. The topography back from the river bank was obtained by running random lines from points along the base. These were similar to the banco traverses described by the author. Most of the elevations for topography were obtained by level, running alongside the transit. The transitman located the controlling points, and the levelman obtained the elevation, which was immediately given to the transitman and entered in his notes. This method requires more instrumentmen, but it is very rapid and simple, and saves much time in the reduction of stadia notes. Where it would have required several "set ups" of the level to obtain the elevation, resort was occasionally had to vertical angles. The true meridian was obtained from a magnetic base established by the U. S. Coast and Geodetic Survey at Victoria, and was checked at a place about 14 miles below the starting point by direct observation on Polaris by the method previously referred to. The field work of this survey cost about $125 per sq. mile. This high cost was due to the bad weather encountered and to the thoroughness with which the work along the river was done. Much of that work has not been described herein. The cost includes also the purchase of considerable equipment, fitting up a houseboat, etc. The survey was made for the purpose of preparing an estimate and report on the improvement of the river by locks and dams. For the area back of the river bank the cost per square mile was probably less than one-half the figure given.

STORAGE TO BE PROVIDED IN IMPOUNDING RESERVOIRS FOR MUNICIPAL WATER SUPPLY.

Discussion.*

BY MESSRS. HIRAM F. MILLS AND T. U. TAYLOR.

Mr. Mills.

HIRAM F. MILLS, HON. M. AM. SOC. C. E. (by letter).—The writer is unable at present to make a critical study of this subject, but would like to ask Mr. Hazen if he has sufficiently provided for the condition —observed many times in New England rivers—that a very small run-off is often followed by a second year of small rainfall, which gives more trouble because following after ponds and ground-water were lowered?

Exceptionally, we have the third very dry year, as in 1911, when storage reservoirs were generally empty, and very great anxiety was relieved by a moderate rain in October and more in November. This third year, of course, he would regard as the exceptional year, when emergency supplies or borrowing may have to be resorted to; but the writer is not quite sure that the second very dry year—which often occurs—is provided for.

Mr. Taylor.

T. U. TAYLOR, M. AM. SOC. C. E.—Among the elements or factors entering into the problem of the storage of water for municipal water supply, the author mentions the following:

1.—The size of catchment area or water-shed;
2.—The mean annual run-off per square mile;
3.—The portion of water area and the loss by evaporation from it;
4.—The natural storage in lakes, or deposits in sands, gravels, or pervious materials;
5.—The regularity of flow.

* This discussion (of the paper by Allen Hazen, M. Am. Soc. C. E., published in the November, 1913, *Proceedings*, and presented at the meeting of December 17th, 1913), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Taylor.

Having spent more than half a century in the West, and having been more than half that time a close student and observer of water conditions in the great southwest section of the United States, the speaker welcomes any discussion of storage problems, even though the data for the most part refer to sections of the country with conditions unlike those of his own. Such discussions are valuable, although they may serve the sole purpose of convincing engineers that the data for the East cannot be applied to the West, and that the man who does this brings disaster on the enterprise and should bring it on himself. However, such discussions are valuable, whether for municipalities, irrigation, or power. In the Southwest, especially in Texas, all these problems have to be considered, and it sometimes happens that two, or perhaps all three, storage problems may occur on the same river.

Two of the elements entering into the problem, as mentioned by Mr. Hazen, can be omitted in Western or Southwestern problems, namely, the water area in the water-shed and the natural storage in lakes. The three fundamental factors in Texas are:

1.—Area of water-shed;
2.—Regularity (or irregularity) of flow;
3.—Run-off.

The area of the water-shed can be ascertained with a reasonable degree of accuracy, and the regularity of flow can, in general terms, be ascertained by local testimony—and it is about the only factor in the problem where the testimony of the oldest inhabitant is worthy of serious consideration. For accurate calculations, however, it would be necessary to have hydrographs constructed from daily records of flow, and these can only be obtained by gauging stations established and maintained with unbroken records of gauge readings and of annual rating curves. The third factor, the run-off, is the one which contains possibilities of the gravest error. Any attempt to apply run-off data obtained in one section of the country to a locality or stream in another section is likely to result in great damage, unless Providence is kind. It is full of the utmost danger, as many wrecks in the West will bear silent and bitter testimony. The regularity of flow, the quantity of daily flow, the mean monthly flow, the mean annual flow, and the run-off are data that can be obtained only by careful observations and measurements for the locality, station, and stream concerned. The run-off for the same stream, at different stations along its course will be found to vary greatly. The speaker calls to mind a case where the run-off on a stream at one point is 0.1 sec-ft. per sq. mile of water-shed, and at a point 1 mile above it is only 0.01 sec-ft. A stream may course its way through a coastal plain of a reasonably flat country, then enter a canyon section where

floods occur with torrential violence, and then again, in its upper reaches, it may enter into a flat upland section. It will be found, and, in fact, has been found, that the run-off and flow in second-feet per square mile of water-shed differ greatly. The problems in the West are largely concerned with the rainfall, run-off, mean flow, and the necessary storage capacity to equalize the flow or to equalize it sufficiently for the municipality, irrigation project, or power problem. Mr. Taylor.

Careful daily records and observations on the Colorado River of Texas, at Austin, Tex., for the last 14 years, have shown that the average or mean flow for this period has been 1 820 sec-ft. The water-shed of 37 000 sq. miles would give a mean flow of $\frac{1}{20}$ sec-ft. per sq. mile. The lowest mean annual flow for this period was $\frac{1}{74}$ sec-ft. per sq. mile, and the largest flow on record, occurring at the time the Austin Dam failed, April 7th, 1900, amounted to less than 4 sec-ft. per sq. mile. The lowest flow on record occurred from August 15th to 20th, 1910, when the run-off was about $\frac{1}{1800}$ sec-ft. per sq. mile.

The mean annual rainfall on the water-shed of the Colorado above Austin for the period was practically 24 in., but the mean flow for the period was only 1 820 sec-ft., which is equivalent to a run-off of 2.88%, or 0.7 in.

With these staggering facts available, a $4 000 000 enterprise was established in a neighboring territory, when, after unusual rains, the engineers awoke to the fact that, in using an assumed run-off derived for other regions, they had omitted the most vital factor, and had, according to their own admissions, over-estimated the possibilities of the scheme by a large percentage. The money had been spent, the water-shed was there, and the rains came, but the run-off refused to run with the vigor that it was assumed to display on such occasions. The only plea of defense is that the engineers were misled, as to the run-off, by a book on irrigation, when the book made no statement as to the run-off in the territory mentioned.

A large municipality authorized the construction of an impounding reservoir and its appurtenances at a cost of $1 000 000, on an assumption of a run-off of 19%, and again there was a failure to come up to expectations.

The run-off is a complex factor, depending on topography, vegetation, kinds of soil (whether cultivated or uncultivated), rainfall, distribution of rainfall as to time of year and as to growth of vegetation, and, what is still more vital, the condition of the soil at the time of the rains. Personal observation has convinced the speaker that a 2-in. rainfall in 24 hours may at one time give a run-off of 25% and at another time no run-off whatever. In 1910 there was the lowest flow of the Colorado River at Austin, but it was not the year of least rainfall, nor the year of lowest mean annual flow. Each stream is a

Mr. Taylor.

problem unto itself. An experienced engineer will go very slowly in such matters. Like Davy Crockett, he will be sure he is right, and then go ahead, and not, like many, "rush in where angels fear to tread."

The Colorado of Texas has a canyon section or power section, a municipal section, and an irrigation section. At present, due to a lack of storage, neither the power section nor the irrigation section is reliable as a revenue producer, as the flow is spasmodic and irregular. The construction of storage reservoirs on this river is a simple and entirely feasible problem, and it would be an easy matter to store about 20 000 000 000 cu. ft.; and this, in the driest years, would give a minimum flow of 800 sec-ft., which, with the total head of 240 ft. that could be obtained by the various dams, would give about 20 000 h.p. Then, in addition, this reliable and equalized flow would insure the irrigated rice crop 250 miles below, near the coast. Altogether, the Colorado offers one of the best problems for storage known to the speaker. Its records as to flow, area of water-shed, run-off, dam sites, and the demand for power and for reliable flow for irrigation, have all been worked out, and there need be no assumptions as to any factor.

The method suggested by Mr. Hazen for rating the dry years is safe, and would fit any section of the country, because each river would be writing its own biography. It might sound a little more comforting to the people of the West if the percentages were given in "wetness" instead of "dryness". The dryness feature is obtruded on them with sufficient emphasis already, because it is a land

"Where the prairie dog kneels,
On the back of his heels,
And silently prays for rain."

THE DEPRECIATION OF PUBLIC UTILITY PROPERTIES AS AFFECTING THEIR VALUATION AND FAIR RETURN.

Discussion.*

By Messrs. W. J. Wilgus, J. E. Willoughby, Frank C. Boes, Allen Hazen, H. C. Vensano, Leonard Metcalf, William B. Jackson, F. Lavis, Alexander C. Humphreys, Henry Floy, Clinton S. Burns, Stuart K. Knox, and J. H. Gandolfo.

Mr. Wilgus.

W. J. Wilgus, M. Am. Soc. C. E. (by letter).—The distinction made by Mr. Alvord, that the formal setting aside and labeling of depreciation reserves should entitle the owner of a property to a return on the full cost of its reproduction new, and that the non-observance of this technicality should deprive him of that right, does not appeal to the writer as being just or logical. Surely, if the general balance sheet of a corporation shows an excess of assets over liabilities sufficient to offset the accrued depreciation of the property, there would seem to be no more reason why the return should be based on an impaired investment than that the rent paid by a tenant should be lessened if the owner, who has agreed to keep the premises in repair, elects not to maintain a special fund therefor in the bank.

The majority of railroads have ample profit and loss surplus accounts invested in outside securities or in the property in excess of the amount on which a fair return is earned; and this surplus, for all practical purposes, is a depreciation reserve which insures the ability of the corporation to meet its liability of paying for maintenance out of income. A failure by a corporation properly to meet its liability

*This discussion of the paper by John W. Alvord, M. Am. Soc. C. E., published in the November, 1913, *Proceedings*, and presented at the meeting of December 17th, 1913, is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Wilgus.

of maintaining the property out of the rate, is usually the result of over-payment of dividends, and eventually brings its own punishment through the necessity of a reduction or suspension of dividends during the period of rehabilitation. This course is obligatory, as charges for rehabilitation legally can only be made through income.

Whether or not a depreciation fund is actually set aside would seem to be immaterial. What the public is interested in is the proper upkeep of the property without an increase, for that purpose, of the capital burden which it is expected to bear through the rate.

As Mr. Alvord states, "* * * no amount of accounting or theorizing can make good a depreciation fund which is actually not in hand"; but to determine whether or not it is in hand may be done just as effectively through an examination of the balance sheet in conjunction with a valuation of the assets, as in looking for a labeled fund in the bank. To "fine" the owner who elects to protect his liability in some other form than by means of a special fund, seems to be rather a drastic punishment for his selection of one of two alternative treatments of an accounting detail.

Mr. Willoughby.

J. E. WILLOUGHBY, M. AM. SOC. C. E. (by letter).—Few engineers will disagree with Mr. Alvord's suggestion,

"That if a sinking fund * * * for depreciation is actually kept * * * in trust as part of the property, it should * * * receive the same rate of fair return as the remainder of the property 'used and useful for the public.'"

The writer, however, believes that this suggested addition to the capital account will find little favor. Depreciation is an operating expense when applied to the accounting of a going public utility, and there is no more reason for capitalizing the depreciation item of operating expenses than for capitalizing any other single item, for instance, the wages paid to enginemen in charge of railway trains.

Furthermore, such funds have not been generally provided as a part of the capital account of our public utilities, and we gain directness by discussing the actual conditions, and the need of providing for depreciation as an operating expense, so that the accounting will always show the value of the public utility for any purpose, rate-making or otherwise.

The accounting of a public utility covers other things than the cost of the plant, and it is the ultimate finding of the accounting (exclusive of the speculative and intangible features) that fixes the value of the utility. The author, however, limits his discussion to that "line of evidence as to value known as the reproduction method, or cost new less depreciation." By thus disregarding all other elements of value that enter into a public utility property, the author has no credit account to offset depreciation, except the cost of reproduction

Mr. Willoughby.

new of the physical property of the utility, and he would limit the rates to be charged by the utility corporation to a reasonable return on the capital necessarily expended for a new plant less the accrued depreciation. This means that the utility corporation must, immediately after reproducing its property new, write off as loss the amount of the accrued depreciation, although that accrued depreciation has actually resulted from service rendered to the public, and, although the only practical way of reproducing the physical property will be to invest first capital to the extent necessary to reproduce the property new.

It is generally accepted that the reproduction of the physical property of a public utility which has been in operation for some years so as to show its exact stages of depreciation would be at a greater cost than to reproduce it with all new materials. Consider the difficulty and expense of providing and assembling into a completed structure the curve-worn rails, the partly decayed ties, the partly fouled ballast, the partly failed bridges, trestles, and culverts, and the argument is completed. Consider then the injustice of the suggestion of the author that the property owner should be penalized because of the impossibility of assembling his plant, except as a structure composed of new elements. What the public pays for is service. If the service is satisfactorily performed, as in the railway after some years of operation, over rails, cross-ties, and ballast, each exhibiting but 55% of their cost new, less salvage, and if to perform that service it has been necessary for the owner to expend in the past 100% for those items, the owner should receive a reasonable return on that 100 per cent. The public's protection lies in scanning the operating expenses to see if the charge for maintaining the property is unduly high, as a result of the failure of the railway company to make provision in the past for the depreciation at the time the depreciation actually occurred, and not to deduct from the capital originally expended the amount of the accrued depreciation. It is only after the operating expenses are deducted that any return can be made to the owners of the stocks and bonds. If the operating expenses are unduly high, on account of failure to make provision for the depreciation as it had accrued in the past, the penalizing of the owner occurs in the denial of deduction from the gross earnings of so much of the alleged operating expenses as is due to the failure of the owner to provide for the depreciation at the time of its accruing. The method of penalizing the owner, as suggested by the author—the deduction of the accrued depreciation from the reproduction cost new—is a confiscation of property to the amount of the accrued depreciation, because the amount of the accrued depreciation was originally and necessarily put into the property before any depreciation could take place, and whatever has taken place

Mr. Willoughby.

is properly to be regarded as an expense of operation. No engineer would deduct from the physical elements of a property the operating losses due to bad financial arrangements, extravagance, or incompetency.

To illustrate further: take a cross-tie costing 80 cents in place, and lasting 8 years. For each year following the placing of the tie, there should be charged out as operating expense the sum of 10 cents (less by such interest as it may earn), as the proportion of the cross-tie consumed in that year's operation, so that when the cross-tie is replaced in the eighth year only 10 cents of its replacement cost would be charged into operating expenses, the other 70 cents being taken from the depreciation fund. The purpose of the depreciation fund is to distribute the operating cost of renewal over the number of years that has been taken to consume the tie. Where a depreciation fund has not been accumulated to offset the actual depreciation, the monetary value of such depreciation will go into the profit and loss account as a debit, but there may be such values in that account—like accumulated reserves—which will entirely absorb the debit. Depreciation, when regarded as an operating expense, can never be used to lessen the reproduction cost of a public utility. It will always affect the value of the utility as a going concern.

Every public utility should make provision in its accounting for depreciation, because such an account is necessary to show the annual operating cost of any plant, and to reflect in the accounting the financial and physical condition and value of the plant. It should cover "all the losses of value that occur in the property, plants, or parts thereof, from wear and tear, obsolescence, or inadequacy."

For a public utility that has permitted the depreciation to accumulate without providing for an actual fund to offset the same, then the amount of such accrued depreciation (in such event a debit) will go into the profit and loss account, there to be offset by the credit items of other accounts. Correct accounting does not require the actual presence of cash, except as to the amount of the item of cash on hand.

As to what rates are necessary for a fair return for any public utility, if confiscation is not to result to the property in the legal sense: the suggestion is made that the rates should be sufficient to provide for:

1st.—The payment of taxes and other public dues;

2d.—The payment of all operating expenses, including as a part thereof a charge sufficient to care for the annual depreciation that takes place;

3d.—The payment of a reasonable commercial interest (commercial interest being one that considers and includes the element of risk involved) on the reproduction cost new of the property, including the necessary working capital;

Mr. Willoughby.

4th.—The payment of a like interest on the intangible values of the property and the unearned increment;

5th.—And, finally, the accumulation of funds sufficient to provide for the non-earning additions demanded by the public. The commercial interest earning additions and betterments can be capitalized and becomes a self-supporting part of the cost of the plant.

Mr. Boes.

FRANK C. BOES, ASSOC. M. AM. SOC. C. E. (by letter).—After reading Mr. Alvord's paper, the writer tried to picture to himself some of the possible results of putting such a system of rate-fixing into general operation.

Consider two adjoining and otherwise similar communities served by two power companies, the one having an old and decrepit plant, but still capable of rendering efficient service, and the other having a new and up-to-date plant. The large users of service, of course, would gravitate toward the community served by the depreciated plant, thereby decreasing property values and rents in the community which they left, and making it impossible for the new plant to compete with the old one. The continual see-sawing of rates, due to periodic repairs and renewals, would make it impossible for service rates to reach a standard level, thus making it impossible for a consumer to foretell what his next year's bill for service would amount to, and would also cause much litigation and confusion.

To fix rates purely on a basis of physical value, would remove incentives for good management and economy, and put a premium on wastefulness, expensive plant, and unnecessary repairs and renewals. Over-expenditure on plant, for the sake of keeping the rate up, is more to be feared than a reasonable amount of decrepitude, for, after all, the service rendered is what is paid for.

If such a system were in vogue now, those who live on Staten Island would be paid a substantial sum for riding on trolley cars which have long outlived their years of usefulness and are run by a plant which is in the condition of the "one-hoss-chaise." They are consoling themselves by the thought that they pay, not toward earnings on a dilapidated outfit, but for the service rendered—a 5-mile ride. A company owning a modern plant might give worse service.

Mr. Alvord states that the average life of the component parts should give the composite life of the plant. This must be an oversight on his part, for, assume a plant to consist of two parts, A, costing $10 000 and having a life of 5 years, and B, costing $5 000 and having a life of 20 years. Surely the composite life of the plant is less than 12½ years, for its major part is renewed twice in that time.

In fixing rates by such a method, one must also consider that the depreciation curve is not a straight line. It is permissible to establish

Mr. Boes.

a depreciation fund by the straight-line formula, for that is merely a convenient method by which the owner may distribute his renewal costs evenly. The amount of the depreciation fund by no means represents the actual physical depreciation, and to base the deduction of rates on an amount which is taken arbitrarily, and is greater than the actual depreciation, would be unjust, particularly if the service were still unimpaired. When a laborer reaches old age, his earning power is greatly reduced, but is he worth less at thirty-five than at twenty? One cannot expect to deduct $3 000 from a $10 000 plant, in fixing rates, and still have a $10 000 service maintained. If the returns are not based on the entire investment continuously, the investment will not have renewed itself at the end of the plant's term of life, and the owner will not have the plant that he had to begin with. Depreciation is merely another form of capital, and must be kept continuously earning returns on its entire amount.

It seems unjust to expect to pay less for service in the fifth year, the service being exactly the same, merely because some parts of the plant will require replacement at a date then nearer than in the first year. Does one pay less for milk given by old cows or for apples grown on old trees?

Mr. Alvord intimates that the reduction in rates should be considered in the nature of a fine, but surely it would be unjust to have a fine imposed, if, when the time for renewals actually arrived, the owner produced the funds and put the plant in shape. What then? Would the amount of the fine which he had paid be returned to him? A man cannot be fined because it is thought that he is going to commit a crime.

An argument sometimes advanced, and by the Courts, is that one should not make one valuation for rate-making purposes, and another valuation for the purpose of sale or purchase; that is, if valuation is deducted in making a sale of a plant, it should be deducted in making the rates of service. Consider some private business: If an owner wishes to sell his factory, he must certainly make a deduction for depreciation, but the price of his merchandise is not affected in any way by the age of his factory or by the condition of his plant. Neither do his customers inquire as to whether or not he has an adequate renewal fund actually in hand. That responsibility rests with himself alone.

Though there is a difference between fixing the prices in a private business, and fixing the rates of a public utility which enjoys monopolistic privileges granted by the public, the fundamental principles remain the same in each case.

The approaching repairs and renewals are an obligation and a cause of worry to the owner, and to him alone. He has to pay for them, and

the consumer is in no way concerned with it, as long as the service remains the same. The consumer is not concerned with how near the day of collapse the plant may be, as long as the collapse never occurs. The consumer is concerned only with impairment of service. When that occurs, then a fine may reasonably be imposed. Mr. Boes.

In fixing rates, one need only be sure that the property is in satisfactory working order and that proper service is being given. The owners can then be left to worry about the depreciation for themselves.

ALLEN HAZEN, M. AM. SOC. C. E. (by letter).—Depreciation has to be taken into account in both the operation and valuation of public service properties. It has to be taken into account because it is one of the fundamental facts that cannot be ignored. Mr. Hazen.

The writer is familiar with depreciation, especially in water-works properties, and what he has to say relates primarily to them.

Allowances for depreciation have actually been made in nearly all properties of this kind. This is not the less true because the amount allowed has not been determined in a rational manner, and frequently has not even been called depreciation. In most public works the first cost has been paid by money raised by the sale of bonds, and a sinking fund has been established, and annual contributions made to it, intended to be sufficient to provide for the payment of the bonds when they became due. This, in reality, providing for depreciation, even though the word "depreciation" is not used.

Another way of providing for depreciation which has been common, has been to pay for new construction out of earnings. This also is an efficient means of allowing for depreciation, although the methods and amounts to make it efficient have seldom been carefully thought out. In general, with publicly owned properties, the allowances that have actually been made for depreciation in these ways have been above the truth. This has been fortunate, as the excess has represented only a slight addition to rates which have not been burdensome, and the resulting strong financial condition of the works has tended to good service, worth more than its cost to the takers.

In the relatively small number of cases where no allowance, or an inadequate allowance, for depreciation has been made, there results sooner or later a cramped financial condition tending to bad service, and equally unfortunate for the works and for the takers.

The measure of depreciation for any period is the decrease in the fair value of the property under discussion, or any part thereof. In valuation proceedings, where the cost of reproduction is being considered, the decrease in the value of the property, as compared with the value of corresponding new property, is the measure of depreciation. The fair value of the property is to be considered always as the fair value between a willing seller and a willing buyer. To take

Mr. Hazen.

a concrete case, it may be considered how much less a willing buyer would probably pay and a willing seller take because the pipes in the streets had been in use for a time, and had suffered the depreciation naturally incident to use. Obviously, some deduction would be made. The carrying capacity of the pipes is less than that of new pipes, owing to rusting and tuberculation; there is more leakage from the joints in old pipes than in new ones, representing loss of water and profits. It may be presumed that the pipes in an existing system laid from time to time are perhaps less efficiently arranged as to sizes and locations than would be the case in such a pipe system as the buyer would lay for himself. These would probably be the most important points to be considered as between the buyer and the seller in deciding what deduction was to be made. In addition, any peculiar conditions of any kind affecting the value of the property would be duly considered.

The average age of pipes in any system in a growing city will ordinarily be from one-third to one-half of the age of the system, and seldom more than 15 or 20 years. The bare fact that an average of 15 years has elapsed in a possible ultimate life of from 75 to 150 years, which is assumed by the author, would have but little influence between a willing buyer and a willing seller.

The case is somewhat different with boilers, which may be assumed to have a life of 20 years, or some other definite period, and will then have to be replaced. The boiler represents the exceptional case in water-works affairs, and not the ordinary one.

The writer believes that there is no such thing as a period that can be called the life of cast-iron pipe. Different pieces of pipe may have useful lives ranging from a few hours to periods so long that they extend beyond our experience. Any statistics that could be collected would contain records of pipes that had been discarded for one reason or another, and would contain, at best, only estimates of the remaining life of the very important part of all the pipe laid that is still in service. The estimates of the remaining life of this pipe cannot be considered to have much value, and averages based on them are certainly no better. Even if the average life of pipe could be ascertained in some statistical way, it would be of little service. What is really wanted is the average percentage payment on the value of all the pipe to be made each year to make good the depreciation lost in it, and this percentage is undoubtedly quite different from the depreciation computed by the sinking-fund method from the average life of pipe, if it could be ascertained.

The writer believes that in the case of cast-iron pipe the gradual reduction in carrying capacity, the increase in leakage from the joints, and the fact that a system now designed might better serve its pur-

pose than an old system, are the dominating factors, and that the elapsed period of life is of secondary importance.

It may be suggested that in using the sinking-fund method it is possible to assume a life for pipe to give any rate of depreciation that is desired, and as the assumed life is pretty sure to be beyond the experience of the ordinary water-works system, it cannot easily be shown to be fallacious. Thus, with a 4% sinking fund, the depreciations corresponding to several lines are as follows:

30-year	life,	1.78%	annual	depreciation
40- "	"	1.05%	"	"
60- "	"	0.42%	"	"
80- "	"	0.18%	"	"
100- "	"	0.08%	"	"

Of course, the percentages given refer to the structures only when new. By the sinking-fund rule they would steadily increase with increasing age.

The ease of selecting a life to give any desired rate of depreciation is obvious. Considering the great difficulty, or perhaps rather the impossibility of securing statistics to show the true average life of cast-iron pipe, it may be questioned whether, as a matter of fact, the process has not been reversed, perhaps unconsciously, by estimators, and a life selected which would give a rate of depreciation which has seemed to them reasonable, as judged by other standards. If this is really the case, then the use of the sinking-fund method for computing depreciation may be regarded as a kind of mental exercise tending to familiarize the estimator with the workings of compound interest during long periods, and thereby to aid in keeping him from reaching unreasonable conclusions.

The sinking fund has this to recommend it: that it corresponds with practical experience to the extent that depreciation in the early life of a structure goes on slowly, and that as the years go on the rate is increased. There is a tendency to substitute a rule of calculation for judgment, and, as far as the basis of the rule can be well established, this is desirable; and, if a fixed rule is to be used, probably the sinking-fund method of computation is the safest that has been thus far proposed, but it must not be supposed that the real basis of the sinking-fund method is the actual determined life of the structures. It is, instead, the life which practical appraisers find will give rates of depreciation that are in accordance with their experience.

The writer believes that the most logical way to estimate depreciation in the appraisal of a plant is to consider each item on its merits, to determine and take into account its physical condition, its usefulness in the service and the state of the art, and the possibility of substituting other and more efficient structures to perform the ser-

Mr. Hazen.

vice rendered by it. The excellence of the design must be especially considered, and depreciation may be several times greater on a clumsily designed structure than on a well-designed one, although the durabilities and lives may be the same. In a similar manner, a well-built structure suffers less depreciation than one not so well built.

Improvement in methods of pumping, filtering, laying pipes, or performing any part of the service, all have their bearing on the depreciation of similar parts of an old plant. The rule must always be to find what deduction would fairly be made because of all the conditions that exist between a willing seller and a willing buyer fully informed as to those conditions.

In estimating the amount of depreciation to be written off each year, the writer believes that one of the best kinds of information is to be obtained from the financial histories of old plants in connection with appraisals. The question may then be taken up as to whether an annual depreciation of 1% on the cost of reproduction of the property from year to year, made during the whole life of the plant, would have served to have brought the book value to an amount reasonably near the estimated cost of reproduction at the time of the appraisal, and if not, to find as nearly as may be what percentage thus allowed annually would have sufficed to do this. Data of this kind are hard to get, but the engineer having to do with appraisals occasionally has opportunities to secure them. Valuable as these data are, they must be used with caution, as the depreciation of the future is not necessarily measured by that of the past.

The method of allowing for depreciation in the annual operating account is an important matter. The writer recalls the case of trustees who had undertaken the management of an important water-supply system, and who were confronted on the one hand with the difficulty of raising money for urgently needed extensions, and on the other of being required by law to take up a business entirely foreign to that for which they were appointed, namely, that of setting aside a certain proportion of the income from the operation of the property and investing it in securities to be held against the redemption of bonds when they became due. The situation was a trying one, and one that ought not to have existed.

The sinking fund was invented to protect the bondholders who might think that otherwise the city would not be able to raise so large a sum of money on the maturity of the bonds. That is the only possible justification for its existence. If we grant the solvency of the city or company, and assume that they will be able to refund the bonds when they become due, it is better in every way that the allowance for depreciation, or the sum that would otherwise be put into a sinking fund, should be invested in the plant as far as there is need of it.

Mr. Hazen.

The author does not know of any sinking fund that has been established for the especial purpose of meeting depreciation. Such a fund as he suggests would be one to which annual depreciation allowances would be paid, and from which money would be taken to replace worn out or discarded parts, and the amount of such a fund, he thinks, would not often exceed 10 or 15% of the value of the plant. The writer feels that the question of whether such a fund is necessary or desirable must be left to those who operate the plant. If it is desirable, he suggests that it might be more appropriately called "working capital", as its function would be quite different from that ordinarily covered by the term, "sinking fund".

It is the writer's feeling that, so far as such a fund of working capital is reasonably necessary and desirable for the proper and economical administration of the plant, the amount of such fund might properly be taken into account in fixing the rates that might be charged without exceeding those that would yield a fair return on the property; but he sees no reason for taking into account otherwise any part of the value of the original plant that may have been lost by depreciation in making such rates. It is clearly the privilege and duty of public service corporations to charge rates that will permit marking off a proper allowance for depreciation. When this allowance has been once determined and marked off, there would seem to be no equitable reason why the capital thus marked off should be further considered in connection with the question of fair rates.

Mr. Vensano.

H. C. VENSANO, ASSOC. M. AM. SOC. C. E. (by letter.)—in looking over this interesting paper, the writer was surprised to find the argument that, unless a sinking fund for depreciation is actually in bank or in trust, it should not be considered a reason for not deducting depreciation in valuations for rate-making purposes.

In his summary, the first and second arguments indicate that Mr. Alvord feels that even if a sinking fund exists, reinvested in the plant itself or elsewhere, it should not be considered as such.

To the writer it seems axiomatic that, if a sinking fund, properly handled and accounted for, exists anywhere at all, its existence is a good reason for the non-deduction of depreciation in valuations for rate-making purposes.

If a sinking fund to cover depreciation has been provided, and if it has been properly handled, and if, as a matter of course, the returns from such fund, in no matter what form they are received, have been turned back into that fund, it would seem clear that it is immaterial whether such fund exists in bank and trust, in the property itself, or elsewhere.

Mr. Alvord seems to feel that, even with proper funds reinvested in the property and accounts properly kept, such accounts are merely

Mr. Vensano.

the opinion of the owner as to depreciation which has accrued on his property, and further argues that when a fund is handled in this manner the owner will have a return on it as a sinking fund and "at the same time have a return on it as a betterment to the plant," and that "this would be an obvious injustice to the public."

If the fund is properly kept, the accumulations from such investment, of course, will go into the sinking fund itself, and no portion of it will be returned as dividends to the owner, and in such case no injustice to the public would follow and no duplication of returns on investment would be made by the public to the owner. The whole point hinges on the proper accounting, and with such proper accounting the public's interest will be entirely safeguarded. As a matter of fact, any sinking fund, whether in bank or elsewhere, is now largely an "opinion of the owner" as to the depreciation on his property, or rather on the rate at which it is likely to occur, and will always represent either the owner's opinion or the opinion of some rate-making or controlling body which he has accepted, or has been forced to accept.

Assume a case in point, and see if any excess burden is thrown on the public. Take a large utility of complex properties, which utility may be considered of such a nature that after a number of years the necessary yearly depreciation replacements would arrive at practically a constant amount (assuming no extensions or betterments as occurring). Assume an original investment of $100 in complex properties having an average life (say, 40 years), such that $0.83 set aside annually as a depreciating increment will produce the proper sinking or replacement fund. Now assume that the property has been in existence so long that annual depreciation replacements have become constant (no betterment or additions considered), so that at this time the sinking fund in bank or elsewhere has reached a total of $33.40, all replacement made in the meantime having been paid from it, and that now the balance has been reached such that the annual increment set aside and the accruing interest on the $33.40 will just pay for the annual replacements, that is, the cost of annual replacements has practically become constant.

Also, for convenience, suppose that the interest rate on this sinking fund (assumed to be in the bank) is the same as the dividend rate to the owners of the utility. Now, in this case (Case 1), the fund is actually in bank, rates of dividend and interest are 5%, and rates have been fixed by a rate-making public service body so that they will provide such dividends plus the necessary depreciating increment of $0.83, as previously mentioned. Table 1 then shows the result.

Now (Case 2), it may also be that extensions and betterments have been made so rapidly that the sinking fund, instead of having been banked, may have been reinvested in the property itself; let it be supposed that this has been done. The public, of course, will furnish

Mr. Vensano.

TABLE 1.—CASE 1.

			Paid by Public.		Paid by Bank.		Available for Replacements and Reserve.		Available for Dividends.	
			Rate.	Amt.	Rate.	Amt.	Rate.	Amt.	Rate.	Amt.
Original investment	$100.00	Allowed as profits	5%	$5.00						$5.00
		" for depreciation reserve	0.83%	0.83				$0.83		
Sinking fund in bank	33.40	Interest			5%	$1.67		1.67		
Investment in betterments, through later security issues	33.40	Allowed as profits	5%	1.67						1.67
		" for depreciation reserve	0.83%	0.28				0.28		
Total paid by public				$7.78						
" " " bank						$1.67				
		Total for depreciation reserve						$2.78		
Total investment	$133.40	Total available for dividends							5%	$6.67

TABLE 2.—CASE 2.

			Paid by Public.		Paid by Bank.		Available for Replacements and Reserve.		Allowable for Dividends.	
			Rate.	Amt.	Rate.	Amt.	Rate.	Amt.	Rate.	Amt.
Original investment	$100.00	Allowed as profits	5%	$5.00						$5.00
		Allowed as depreciation increment	0.83%	0.83				$0.83		
Depreciation reserve reinvested as betterments	33.40	Allowed as profits on depreciation reserve	5%	1.67				1.67		
		Allowed as depreciation increment	0.83%	0.28				0.28		
Total paid by public				$7.78						
Total investment	$100.00	Available for dividends							5%	$5.00
		Total to depreciation reserve						$2.78		

NOTE.—The total, $2.78, to depreciation reserve, represents $2.50, the constant increment on original investment (after 40 years life) and $0.28, a depreciation increment on depreciation reserve (Case 2), or investment in betterments (Case 1). This is proportional to depreciation increment originally provided on original investment.

Mr. Vensano.

the returns through the rates. The results are shown in Table 2. In Table 1, it has also been assumed that similar betterments have been made through money provided by an issue of new securities.

For proper accounting, if, in Case 2, $33.40 reinvested is still maintained in the accounts as a depreciation fund and its increment of earning is returned to such fund (as would be the case were such fund held in bank, as in Case 1), and if the dividends are then paid as before on the actual investment, exclusive of the sinking fund, it will be seen that the public pays and the owners receive the same amounts in each case.

It must be borne in mind that the annual depreciations on additions or betterments have not arrived at a constant stage as yet, and therefore the same proportionate annual expenditure for replacement is not necessary on such part of the property as on the original assumed properties. It is to be noted, however, that there has been provided and set aside a depreciation increment on the amount spent in betterments, which is exactly proportional to that provided on the original investment. Therefore, if the proper increment, or proper average life for the original investment has been assumed (the additions and betterments, of course, being of the same class of properties), the proper sinking-fund increment has therefore also been provided on such additions and betterments.

This would seem to show clearly that, with correct accounting, sinking funds may be very properly reinvested in the property without extra cost to the public. As a matter of fact, as Mr. Alvord pointed out, the returns on a bank sinking fund will be less than the returns from similar funds reinvested in the property itself, and therefore the public would ordinarily actually be benefited by such reinvestment, in that the depreciation increment, which must be included in the rates paid, could be reduced.

This should show clearly that a reinvested sinking fund is certainly not a matter of mere bookkeeping.

It may be argued that the fund is not as safe when thus reinvested, but the assumption must be made that, under public service rate regulation, the rates will be adjusted upward when necessary as well as downward, so that a constant and safe return will be obtained from public utility investments, and, if this is done, the reinvestment of money in the property will be the safest possible method of handling such funds.

If public utility investments are not made safe under Government regulation, Government regulation will certainly fail as such, and either destroy the utilities or necessitate Government ownership; because, with uncertain interest returns, held at a low rate, no capital will be obtainable for investment in such utility.

Mr. Vensano.

It may also be argued that, up to the time where dividend returns on the sinking fund have reached the state of balance and become sufficient to cover the annual depreciation replacement, a fund reinvested in the property is not in such shape as to afford ready use as cash.

It is to be noted, however, as Mr. Alvord says, that large replacements can generally be foreseen a number of years in advance, and a new issue of securities can then be provided to cover such replacement; the betterments constructed under the original sinking fund can be then transferred to capital account under the new securities issued, and the depreciation account credited with the replacement expenditures.

A similar reasoning will hold for any outside investment, provided such investment is safe, and provided the returns from such fund are turned back into it and the whole held as a part of the utility, and, as an additional advisable qualification, that such investment be in liquid form. That is, it might be an investment in bonds of other companies which have a ready sale, and may therefore be considered as liquid. Certainly, no one could object to an investment in Government bonds as being any less safe or less real as a sinking fund than such fund held in bank or in trust.

The writer would also like to add that, in addition to believing that any properly kept sinking fund is a good reason for not deducting depreciation in valuations for rate-making purposes, he also believes that, even in some cases where such fund does not exist, it may be proper to omit the deduction of depreciation. Perhaps it would be better to say that the writer believes that depreciation in general should not be deducted, except in cases where it is clearly shown that the property has been mishandled by the payment of excessive dividends, or mismanaged in some other way, whereby the accumulating of a sinking fund has been prevented, or when such fund has been mismanaged.

Take, for instance, the case of a company which has gone into business recently in proportion to the average life of its properties and equipment. Assume that such company has been in business 10 years, with an average property life of 30 years. In many cases the property might not have paid during its early life, and with the rates at present in force has just arrived at the point where it is able to set aside money for a replacement fund and to pay dividends. Assume that the earnings are sufficiently large to supply a depreciation increment which in the remaining 20 years of life will give the total fund required, which fund, theoretically, should have been started 10 years previously with a smaller depreciation increment. Would it be fair, then, to such company, which has received no return on its investment, and has been unable, because earnings were too small, to provide deprecia-

Mr. Vensano.

tion increment, to cut its rates now to a basis fixed by a depreciated valuation. Such property without regulation could no doubt be considered a good and well-handled investment, as business investments go, and still would be placed among the class of failures if its rates were calculated on depreciated valuation, as just shown. In any event, if rates in this case are to be based on such depreciated valuation, it would seem only equitable to make them sufficiently high to afford a depreciation increment large enough to return the entire investment in the remaining life of the plant.

It is admitted, of course, that, in using valuations from which depreciation has been deducted, rates can still be fixed logically and equitably by a proper handling of such depreciated valuation and by allowing earning to cover a depreciation increment based on the remainder of the life of the property, as shown by Mr. Grunsky in the paper to which Mr. Alvord has referred.

The whole question as to whether or not depreciation should be deducted from physical valuations for rate-making purposes would seem to the writer largely a matter as to whether or not the public utility had been handled correctly. It is his opinion that Mr. Grunsky's theory is entirely correct, and, as theory, could be applied to any rationally handled property. It would seem that no theory of any kind can be made to apply to a property which has not been handled reasonably and honestly by its management, and at the same time be made to apply equally to a well-managed property.

Where a property has been earning large returns, and has disbursed them as fast as earned, and over and above a reasonable dividend rate; and where, at the same time, no sinking fund has been provided, it is clear that such company has shown itself ignorant of depreciation results as a whole, and therefore must suffer the penalty.

This, however, would not seem to disprove the theory as such, and as argued by Mr. Grunsky, that, in general, depreciation should not be deducted in physical valuations for rate-making purposes.

Mr. Metcalf.

LEONARD METCALF, M. AM. SOC. C. E. (by letter).—Mr. Alvord's interesting paper illustrates anew by what different mental paths different men have reached similar conclusions.

As the writer's views on depreciation are consonant with those set forth by the Special Committee of this Society on the Valuation of Public Utilities in its report which will be in print before this discussion, the writer does not purpose to do more than call attention to certain points in the application of the equal-annual-payment method of figuring depreciation, as compared with the ordinary sinking-fund method referred to by Mr. Alvord. The fundamental difference in the two methods consists in the fact that under the equal-annual-payment method, depreciation is treated as an annual amortization or repayment of capital (renewals *per contra* being treated as new con-

Mr. Metcalf.

struction), and the necessary accretion figured on the sinking-fund basis is assumed to be paid to the owner with the annual uniform depreciation allowance, figured on the sinking-fund basis; whereas under the ordinary sinking-fund method of treatment the necessary annual contribution is made to a sinking fund which must be kept intact until the amortization of the item of property under consideration, in order that the fund may earn its own accretion. Under the former method the depreciation allowance is actually deducted from the value of the property, and the fair return is predicated on its depreciated value. Under the latter method, although the fair return is predicated nominally on the depreciated value of the property, the sinking fund must be allowed to earn its accretions, and, therefore, in effect, the fair return, until the sinking fund on any item of property is complete, must be based on the full original value, as otherwise the owner will be denied a portion of his legitimate return. An examination of the table in the Committee's report showing the annual depreciation allowances on an item of property having a life of 20 years, will make this clear.

Under the equal-annual-payment method of treatment, the annual depreciation allowance is increased each year over that of the previous year by the amount of interest or accretion on the payment of the last year, increasing in an item of property having a 20-year life, for instance, progressively from $3.02 per annum on the first year to $7.64 on the last year, if figured on a 5% rate, the sum of the total payments amounting to 100% in the 20-year life. This is in effect equivalent to figuring the depreciation by the sinking-fund method on the original value of the property throughout the period of life of this item, as would be done by the sinking-fund method, it being assumed, however, under the latter, that the sinking fund itself shall earn the accretion.

Why, then, it may be asked, is the equal-annual-payment method to be preferred to the ordinary sinking-fund method? The answer is to be found in the fact that the accounting is perhaps somewhat simplified, and, most important of all, that the combined payments of depreciation and fair return are, with due consideration of the increasing cost of repairs during the life of the various elements of the property, made as nearly uniform as practicable, or, at all events, are made much more uniform than by the sinking-fund method as ordinarily applied.

In its practical application, it has seemed to the writer likely to prove advantageous to establish the approximate allowances to be made for depreciation at intervals of 5 years, more or less, and to convert the estimated allowances or rates of allowance into percentages of gross revenue, rather than percentages of reproduction cost, purely on grounds of expediency and convenience in application. Under such a method it might be found, for instance, that 10% more or less per

Mr. Metcalf.

annum of the gross revenue should be charged off to depreciation or amortization of property—renewals, as previously stated, being charged to new construction. Thus the depreciation allowance would grow annually with the increase in revenue, which is, of course, accompanied with increase in investment and value in property.

To attempt to apply the depreciation allowance as a percentage of reproduction cost involves keeping most careful track of the various elements of property or groups of property having lives of different estimated lengths, adding to and subtracting from these groups new plant built and old plant abandoned—a very laborious and difficult accounting problem. Under the other method of application, book accounts can be kept of the deduction on account of depreciation and memoranda of the property which has actually gone out of service. At the stated periods, then, the more difficult task of comparing the assumptions with the facts developed in the 5-year interval can be accomplished, and any necessary changes in rate allowed can be effected.

Under the equal-annual-payment method and commission control, it does not matter seriously if the allowance for depreciation is somewhat larger than necessary, provided it is not seriously burdensome in the rate, for the reason that the rate-payer immediately benefits in the reduced revenue required, resulting from the amortization of a portion of the property. The owner, on the other hand, does not suffer, as he is repaid an equivalent in cash of the property thus amortized.

Although, theoretically, if no new construction were added to the property, the depreciated value of the property would gradually decrease, as also the fair return, practically, no such condition is likely to arise, inasmuch as public service corporation properties are operated perpetually, and with the growth which is enjoyed by the majority of American cities the renewals and the new construction required will more than offset the depreciation allowance, so that the actual depreciated value of the property will practically be likely to increase rather than decrease, as will, therefore, the amount of the outstanding securities of the corporation. If, for short intervals of time, this should not be the case, then the repayment of capital through depreciation account could be carried in the bank or otherwise invested temporarily until the need does arise, or it can be used in actually reducing the mortgage debt by a retirement of a portion of the bonds, which bonds could be re-issued at a later date when the funds are required.

In the sinking-fund method of applying depreciation, the easiest practical method of accounting the sinking fund is probably the investment of the depreciation account in the bonds of the company, if the funds cannot be absorbed in new construction, and the keeping alive of these bonds, with the re-investment of the coupon interest on them in depreciation account.

Mr. Metcalf.

Mr. Alvord's comment, that if depreciation allowances are not used by the owners of public service corporations in renewals, new construction, or amortization of debt, but are used instead for outside investment, the owners must make recognition of such deduction so far as the public is concerned, is sound; and if these depreciation funds be re-invested in renewals or new construction, the writer is of the opinion that a fair rate of return should be allowed on them as allowed on the remainder of the property, and not simply bank interest rates, for the reason that in such investment in the property, hazard is assumed which must be compensated, and it is further to be borne in mind that there is always some loss in interest in the delay in prompt investment of the sinking-fund surpluses which may accumulate from time to time.

In the case of the equal-annual-payment method, it becomes a matter of indifference to the public how the depreciation funds are utilized by the owners of the property, inasmuch as the value of the property on which the fair rate of return is predicated is decreased annually by the amount of this depreciation allowance, and it seems fair and safe under operating conditions to figure the accretions of annual depreciation allowance to be paid to the owner on the basis of rates at which money could be obtained by the corporation with ample security.

Mr. Jackson.

WILLIAM B. JACKSON, M. AM. SOC. C. E. (by letter).—It is not possible for any one who is truly interested in this subject to read Mr. Alvord's thoughtful discussion without receiving valuable stimulus.

In the case of well-established public utility properties, it does not seem reasonable to consider that a sum of money may with propriety be laid aside in a trust fund of which the amount is determined by the amount which the reproduction cost of the physical property new exceeds the physical value depreciated, in accordance with the rules laid down by Mr. Alvord. There may be possible cases where special conditions, such as hazards of the business, might make necessary the laying aside of a sum of such amount, or even more, but the depreciation element of the property, as defined in this paper—and with which definition the writer heartily agrees—can never justify such a trust fund. As must be readily appreciated by any one who has given this matter careful study, only a relatively small part of such an amount is ever required on account of depreciation in usual public utility properties, and, such being the case, how can any one justly permit of a sum of money amounting to from 10 to 15% of the value of such a property to lie for all time in a trust fund. That is exactly what would be done if a public service company permitted a sum equal to the aforesaid difference to lie in a trust fund, and did not differentiate between the part that might be necessary for use in

Mr. Jackson.

replacement and that which by the nature of things could never be thus used.

In the matter as to whether, in determining the fair value of a public utility property for rate-making purposes, the reproduction value new or the reproduction value depreciated is more important in arriving at a fair value on which the rate of return shall be made, consider for a moment a public utility property from the time of beginning business. At the beginning the company has a right to earn its current operating expenses, a reasonable sum to cover depreciation expenses, a reasonable sum for reserves, and a reasonable return on a fair valuation of its property. If the company is unable to do this during the early years of its existence, it certainly in equity has a right either to add the deficits to its investment on which it may earn a reasonable return, or to have them made up in some other way. When the time arrives when the company can begin to make money, there is no practical reason to require that it shall build up a larger reserve fund than the exigencies of the business require; therefore, it is not logical to assume that the owners have taken out a part of the value of the plant when they have not built up a depreciation fund to an amount which is entirely unnecessary for the most economical and reliable operation of the property. It is equally illogical to assume that any part of the earnings of the property should be considered as constituting such an unnecessarily large fund.

The writer believes that undue importance is placed on depreciation of plant *per se* without due consideration being given to the question whether the property has been kept in such condition as to give substantially as good and economical service as a new property and is fully safeguarded by its reserves from financial breakdown.

In this the writer does not wish to imply any lack of appreciation of the vital necessity for a vigorous carrying out of a safe depreciation programme, and his position in these matters is fully attested in his paper on this subject early in 1910 before the Western Society of Engineers, and in his discussion written in 1911 for the American Academy of Political and Social Science. There is undoubtedly no more unavoidable expense to be met by any public utility company than depreciation expense, that is, the expense for renewals of outused plant.

Mr. Lavis.

F. Lavis, M. Am. Soc. C. E.—It has always seemed to the speaker to be much easier to visualize depreciation and place a value on it than to estimate appreciation properly. He is inclined to agree with the author, that it can be demonstrated, at least from a purely theoretical point of view, that when depreciation is not offset by an actual sinking fund, its value should be deducted in order to obtain the present value of physical property. When, however, valuations of railroads are made for the purposes of rate-regulation or rate-making,

Mr. Lavis.

it seems as if there might be good reasons for not making the deduction.

The discussion which follows is confined to the effect of this theory on the valuation of the properties of railroads, as the speaker's experience has been principally with this section of the industries of the country coming under the general heading of public service or public utilities companies, and though it is probable that the general principles may hold good in any case, there may be some inherent differences in connection with the properties of some of the other sections, such as lighting, water supply, etc., with which he is not so familiar, which when applied to them might modify the conclusions.

It also seems best to confine any discussion of this subject to cases where the depreciation is normal, that is to say, in the case of railroads, where the plant, roadbed, equipment, etc., is maintained in such condition as to give the public reasonably full and efficient service, which with the present close inspection and regulation by the National and State authorities, should be true of most railroads. Abnormal depreciation, in any event, requires special treatment, as a reduction of rates, of course, would not tend to build up a property which is badly run down.

The theory that depreciation should not be deducted when valuations are made for the purpose of establishing rates has been advanced by C. E. Grunsky and W. J. Wilgus, Members, Am. Soc. C. E., in papers recently presented to the Society, and by H. P. Gillette, M. Am. Soc. C. E., in a brief recently submitted to the Public Service Commission of the State of Washington. Mr. Alvord also points out other differences of opinion in regard to this matter, and intimates quite truly that a proper understanding of it is not easy.

If a sinking fund is maintained to cover properly such depreciation as there may be, there can hardly be a difference of opinion that rates should be based on the full value; to this the author agrees. If, however, a sinking fund is not maintained, he claims that the value is not in the property, and, therefore, the public should not be asked to provide interest on such full value. He points out also that, in the United States, sinking funds are not usually maintained. In reference to this it may be noted that a sinking fund of 10% on the capitalized value of our railroads would amount to about $1 500 000 000—much more capital than we can afford to have lying idle.

In order to understand the argument of those who claim that depreciation should be deducted, in cases where a sinking fund is not maintained, take a concrete example: for instance, a new railroad, the value of which, for convenience, will be assumed to be $100, and a fair return on the investment as 7 per cent. Assume, also, that the rates provide for the establishment of a sinking fund.

Mr. Lavis.

At the end of 10 years the road is rendering full and adequate service, though parts of its structure and equipment show signs of wear. The roadbed, etc., in the meantime has consolidated and its value has appreciated. Assume, however, for the purpose of the argument, that after allowing for the appreciation, etc., the net value of the depreciation is 10 per cent. The actual value of the property would then be $90 and sinking fund would be $10.

Under these conditions it will be admitted that the rates should still be maintained to provide the 7% on the amount of the full original investment, inasmuch as the sinking fund produces nothing.

During the period under consideration the annual revenue and expense account of the railroad might be approximately as follows: (Round numbers are taken for the sake of clearness.)

Operating cost	$12
Sinking Fund	1
Interest	7
Total	$20

Now, suppose that during this period the dollar, instead of being added yearly to the sinking fund, is paid out in dividends, which have been 8% instead of 7%, so that at the end of the 10 years the $10, instead of forming the sinking fund, have gone back into the pockets of the owners, then, it is claimed, the public should not be asked to pay rates on the full $100. If the case in actual practice were as simple as this, there would be little need of further argument.

The practice in the United States, however, has not been to establish sinking funds, which produce nothing, but often to put the money back into the property for betterments.

In the case of a new railroad, such as the speaker is considering, as a temporary measure, some of the slopes in the cuts are not fully taken out or not trimmed up until after it is put in operation; the line is not completely ballasted; settlement of embankments has to be taken care of, and so on. Much of this work is done during this first period with the 1% which would have gone to form the sinking fund. Later, the surplus earnings go to provide for reduction of gradients, improvements of alignment, elimination of level crossings, etc.

In Europe and in most other countries of the world, except in North America, all such work is usually charged to additional capital expenditures, and it is largely for this reason that the capitalized value per mile of railroad in Europe is so much greater than in the United States, the capitalized value of English railroads being almost twice as great. There is some idea that railroads in Europe, and particularly in England, have cost more because they are so much better; this,

however, is not so, at least not nearly to the extent of the very much greater capitalization. Mr. Lavis.

In regard to betterments and improvements paid for out of earnings, the argument, of course, is that in a properly made valuation of an existing property, the appreciation due to money spent for betterments and improvements will be duly allowed for, and that when it is, depreciation due to actual wear and tear should be deducted, in order to get the true fair value of the property in use.

If appreciation of the thousand and one improvements in the property of any well-established railroad can be properly allowed for, well and good, but, to the speaker, this seems at least somewhat difficult, whereas there is never any difficulty in allowing sufficient depreciation, so that, after all, the question resolves itself into the ability to make a true valuation of the physical property.

There is no doubt that a fair and just valuation, equitable alike to the public and to the owners, can be made, but that it can be mathematically exact is practically impossible, and because there is so much more probability of over-estimating depreciation and under-estimating appreciation, one may very well hestitate before deducting the former from a valuation to be used for the purpose of fixing or regulating rates.

In most of the valuations which have been made public, the so-called present value has been estimated to be from about 10 to 15% less than the estimated cost of reproduction new. In some cases appreciation due to the consolidation of the roadbed, etc., has been allowed, but apparently the net result is to show a present lesser value, and, according to figures generally accepted so far, the normal depreciation of a well-managed and properly maintained railroad is assumed to be about 10 per cent.

It seems to the speaker that this amount might well be, and probably generally is, offset by what might be called "not easily apparent appreciation." Any railway man of experience can easily imagine work of a physical character done on a well-established road, 20, 30, or 50 years old, which is not easily apparent, the worth of which, however, still exists.

In an article* describing the construction of a railroad recently completed near Kansas City, the Chief Engineer makes the statement that "Owing to the newness of the road, the train schedules are not yet as fast as they will be later."

In another article,† describing some recent new work on an improvement of the Nashville, Chattanooga and St. Louis Railway, occurs the following:

---

* *Engineering News*, October 9th, 1913.
† *Engineering News*, October 23d, 1913.

Mr. Lavis.

"On the new roadbed a heavy bed of cinders is used for ballasting, as this is more easily surfaced during the inevitable settlement of the fills, and forms eventually a good sub-ballast between the roadbed and the permanent stone ballast."

These, of course, are only specific instances of what all experienced railroad engineers know, but it seems as if the importance of this phase of the valuation question is not always fully realized, largely because many of the values thus introduced into a railroad property are not easily apparent.

There is no possible doubt that any of our modern trunk-line railroads are better transportation machines as they stand to-day, with rails and ties partly worn, with other parts of the equipment showing some wear, than they would be if we were able to replace every part in a brand-new condition. Theoretically, by taking specific instances of parts of the railroad machine, such as rails, ties, or rolling stock, one can easily visualize and value the depreciation, but it is known that the well-established railroad, as a whole, is a better and more efficient machine to-day than it was the day it was built.

Knowing this, and there can be no doubt of it, there is something wrong somewhere with a theory which gives a lessened value to a machine which is better than new, and it seems to the speaker that the trouble principally is, not the fact that depreciation is calculated and allowed for, but that appreciation is not appreciated.

In estimating the value, whether for rate-making or for any other purpose, of the purely physical elements of the property of a railroad, depreciation may be estimated and deducted, but one should also be sure that full value is given to the appreciation, to the development costs, and to the other elements which go to make up the efficient transportation machine.

Mr. Humphreys.

ALEXANDER C. HUMPHREYS, M. AM. SOC. C. E.—The reading of this paper should help to emphasize a responsibility which to-day rests heavily on the engineers of the United States; namely, to educate the public and their representatives in legislatures, commissions, and Courts, many of them necessarily ignorant on the questions involved in valuations and rate-making. Here we, the engineers of the country, are charged with an especial responsibility because of our specialized training. First we should, among ourselves, do our utmost to form right judgments on these momentous questions. It is with great regret, therefore, that the speaker finds himself almost completely out of accord with the views expressed in this paper.

We are to-day passing through a period of trial for our form of government. Therefore the speaker feels particularly that, with regard to all public questions, we must frankly express our honest opinions.

Mr. Humphreys.

This is the only way left to meet effectively the mass of bad advice which is being fed to the public.

In the first lines of the paper it is stated: "that space will not be taken here to review fundamentals". The author then proceeds to discuss the very fundamentals of the subject of depreciation, and to support views which, in the speaker's opinion, are fundamentally wrong.

As the speaker understands the paper, the author is attempting to confine himself practically to "the relation of depreciation to cost new", which, he says, is "vital", and that only one line of evidence (reproduction cost new) is to be considered. The speaker is not prepared to agree that "other lines of evidence are equally important before arriving at value".

Mr. Alvord then refers to some writers who have and have not agreed with him, and continues:

"Here, therefore, there seems to be a very serious disagreement, among authors who have written recently on this subject, as to whether or not depreciation should be deducted from the cost new of a property for finding value for rate-making purposes where the reproduction method is adopted as a basis of value. It seems to be desirable, therefore, to present a further study of this question."

Certainly, this paper makes it more than ever desirable that there should be further study of this question. Although the speaker is overwhelmed at the present time with duties accepted, he feels that he would be delinquent if he did not contribute his little share in this much needed discussion.

Mr. Alvord says:

"The sinking-fund method seems to be an accurate way to compute depreciation where all or most of the life history is known, as it consists largely in finding past depreciation."

First, the speaker objects to the use of the term "accurate" in connection with estimates on depreciation to accrue. Again, he objects to the intimation that, it can be assumed as a working basis that "all or most of the life history is known." This life history in large part must depend on the books of account and other records, which frequently are incomplete, and, even when complete, have been influenced by many changes in the system of accounting.

Again, in many cases, the existing company is the consolidation of many smaller companies, the books of which are often not available, and if available are found to be not self-explanatory. It would appear as if it should not be necessary to say to men of experience anything more, or even as much as the speaker has said, on this point.

The author then says:

"The sinking-fund method of computing or allowing for depreciation consists in determining the proper useful life of the structure or machine under consideration".

Mr. Humphreys.

Here he appears to be confusing estimated accruing and accrued depreciation with actual depreciation; but let that be as it may, who shall say authoritatively what is the "proper useful life" of any part of a plant. There are those who assume that the life of parts of plant can be found by reference to tables prepared by so-called experts; but surely this absurdity cannot be supported by men who have had experience as constructors and operators. To determine how much should be allowed for annual expenses or cost, we may well estimate the life of each part of a plant, knowing that these figures may prove to be far from the fact; and hence we are justified in making a liberal estimate for this purpose.

Here, however, we must never forget the underlying reason for this estimate and the journal entries based thereon, namely, to spread the cost of final renewals as uniformly as possible over the periods benefited, so that we shall not deceive ourselves as to losses and consequently as to profits. Especially should we be careful not to over-estimate our profits, and hence we should be sure not to under-estimate the cost of final renewals.

The speaker wishes that the term "depreciation" had never found favor. Much of the present confusion of thought on this subject would be avoided if only the term "final renewals" were used.

Here at once it is seen that such an estimate should not form the basis for determining present depreciation. This should be determined as closely as possible by the exercise of engineering, managerial, and accountancy ability, based on academic and practical considerations, chiefly the latter.

Here we have the all-important difference between estimated accruing depreciation as an element of cost, and actual depreciation in establishing the present value of an asset; this last by actual expert examination, having in mind physical decay, obsolescence, and inadequacy.

Again, Mr. Alvord says:

"In case a portion of the life has passed away, the present value of such structure is assumed to be, in a general way, the present cost of replacement new, less the accrued amount of the depreciation fund to date".

The speaker has just shown why the amount in the sinking fund may properly be quite different from the actual depreciation. It is based on an estimate made in advance, and on many assumptions. In making an appraisal we have before us the present facts as to physical condition, obsolescence, and inadequacy. In the first case we have foresight, and in the latter we have the advantage of backsight.

To determine the actual cost, would one go to an engineer's estimate of the cost of some large construction, or to the record of the money actually expended, which would cover all omissions, contin-

gencies, overhead charges, etc.? If the first course were taken, the speaker fears that the business world would be more than ever critical of engineers' estimates, which have so often misled investors because of the omissions referred to. Mr. Humphreys.

Supposing the existence of an approximately correct determination of the actual depreciation to date, the speaker contends most emphatically that, although perhaps the plant is thus reduced in value, no deduction therefore should be made in a rate-making case.

In meeting this proposition, the question is asked frequently: "Would you pay as much for an old plant as for a new plant?" and the questioner thinks that the question settles the matter.

Not so. As a purchaser, if there were any real depreciation, the speaker would claim a reduction. Why? Because he has to assume the liability for the final renewal of the plant. In a rate-making case, however, that liability still rests on the owner, and therefore the plant must be considered as maintained or to be maintained by the owner.

Mr. Alvord, strangely enough, admits that "no deductions from cost new or reproduction cost, where that method [actual establishment of a sinking fund under trust conditions] is being used, would be necessary". Then he says:

"Where a proper depreciation fund is not set aside actually, but is only estimated and written off in the accounts, there is no such condition, and the matter of writing it off by the owner in his books amounts to only an opinion of his as to what such depreciation fund should be, but does not at all produce such a fund, or make it available; in consequence of which, an appraiser, using the cost new or reproduction method as one of the means of arriving at the value of the property, and finding no depreciation fund actually in hand or in trust, is obliged to deduct it from the property."

Is the appraiser "obliged" to deduct because of an opinion thus expressed?

Mr. Alvord shows that the owner is alive to the fact that depreciation is to be cared for, and that he refuses to inflate his profits by ignoring that fact. By his act he shows that he is liable for the cost of renewal, and that this item of cost must be obtained from income. A buyer would trade on this admission to get a lower price, but, as before shown, even then it by no means follows that the seller would have to deduct the full amount thus written off. That is not a question of the fair determination of values and the fair fixing of rates, but of bargaining.

Mr. Alvord then proceeds:

"In other words, no amount of accounting or theorizing can make good a depreciation fund which is actually not in hand. A clear perception of this principle will save much confusion of thought."

Mr. Humphreys.

Here Mr. Alvord mistakes his assumption for an established fact. The speaker fears that that is a weakness throughout the paper.

The Standard Dictionary defines "Principle", in part, as follows:

"1. A source or cause from which a thing proceeds; a power that acts continuously or uniformly; a permanent or fundamental cause that naturally or necessarily produces certain results. * * * 2. That which is inherent in anything, determining its nature; essential character; essence."

Here, then, it is found that, notwithstanding his disclaimer, as before referred to, Mr. Alvord is discussing fundamentals.

The speaker presumes that much confusion of thought might be saved if all were prepared to adopt blindly Mr. Alvord's dicta and then refuse to confuse their minds by further independent thinking.

Now, to come down to facts: Assets are widely variant in character. Cash is an excellent asset, if the money is honest money. Particularly is it valuable in emergencies because it is liquid. Usually, it is a promise to pay, on the part of the government, of a bank, or, if not in actual cash, it might be a promise to pay by the trustee of a fund; but government or bank promises to pay are not always made good. There has been no little repudiation, even in this enlightened country. Or, government notes may be greatly depreciated. We have also had that experience in the United States, a condition corrected only by the courageous act of a great President now passed to his reward. Still more, the trustee of a fund may default—not an unknown occurrence. Now, if the owner is solvent and agrees to make good the loss due to depreciation, that is, to renew the plant, and this assumed liability is shown on the books, there must be a corresponding asset, or else money not earned has been paid out in dividends. The entries referred to, however, have been made to guard against such a ruinous course. Naturally, the speaker is not referring to fraudulent bookkeeping or fraudulent management, but is following Mr. Alvord in assuming normal conditions and management.

This asset, if not in cash retained, will in all probability appear in additional plant paid for from earnings, and may be regarded as borrowed from the depreciation reserve. The fact is that where the depreciation reserve is treated in this way it has to be borne in mind that all parts of plant which appear in the appraisal inventory as having been paid for from the depreciation reserve fall in one of two classes:

1.—Parts which have been installed as renewals or replacements, and are, therefore, in place of parts represented in the original investment, and hence to be included as such;

2.—Parts of plant which have been installed as extensions or betterments, and have been paid for with money borrowed from the depreciation reserve.

Mr. Humphreys.

These parts, therefore, should be included in the inventory and appraisal, because they are not duplications of investment, but represent additional investment.

In the case of an interest-bearing depreciation reserve, the balance to the reserve should be credited each year with interest at the rate agreed on. Then the money thus borrowed has to be returned when required for final renewals, and must be repaid from capital. In the meantime the company has been able to defer the day for final financing. These extensions and betterments can be considered as capital investments, the amounts borrowed from depreciation reserve standing as a liability against the owners. In reference to this matter, the point may be made again that, whether or not there is a depreciation reserve, the liability for renewals rests against the owners. The setting up of the reserve is, as before shown, to spread this item of loss as uniformly as possible over the periods benefited. The loss due to final renewals will occur in any case, though not exactly in the amount estimated.

Mr. Alvord then attempts to show that the deduction for depreciation would not lead to a progressive reduction in the rates. This discussion he carries on under the headings, "The Attempt to Simplify the Question", "Perpetual Life", "Utilities Commonly Require Growing Plants", "Earning Power of the Depreciated Plants", "Natural Accretions", and "Sinking Funds an Inherent Part of the Plant".

The speaker agrees with some of the statements he makes under these headings; but disagrees absolutely with his conclusions. On page 2053* the author states:

"It is clear, therefore, that, as far as valuation for the purpose of sale is concerned, it is right and proper that, in the absence of actual sinking funds or any sufficient reserve fund, they should be deducted from reproduction cost or 'cost new', when that method is used to ascertain value. Does not this also hold good in the case of valuation for rate-making?"

It is presumed that the author looks for a reply in the affirmative to this question. The speaker unhesitatingly replies in the negative; and this, it is thought, is where Mr. Alvord and his many adherents go astray.

The case of purchase and sale has nothing to do with the question, and the author has supplied, presumably unconsciously, many arguments to support this position. What he has to say under "Perpetual Life," can serve as an example.

What the public is concerned in is the quality of the service rendered. That is the test. It is for the commissions to see that the service is adequate in quantity and quality and that the investment and its return are not exorbitant.

* *Proceedings*, Am. Soc. C. E., for November, 1913.

Mr. Humphreys.

In purchase and sale, it is a case of bargain. It may be a case of turning a fixed asset into a liquid asset. There may be many reasons for the owner's willingness to sell well below value; but in any case he should be willing to deduct fairly for accrued actual depreciation, because the buyer has to assume the liability therefor. If the seller can turn over a sinking fund, which in the opinion of the buyer is a sufficient offset to depreciation, then his liability therefor is covered. All this provided this is the best bargain he can make; for bargain it is.

Under the heading, "The Practical Treatment of Depreciation Accounts", Mr. Alvord takes, as an example of the point he is trying to demonstrate, the case of "a railway having extra rolling stock which is only needed at certain seasons of the year when the traffic amounts to a maximum". Then he shows that the property would not be as valuable if this extra rolling stock were sold, relying on the chance of buying it back when actually needed. Again, the test is one of service. If this rolling stock had been sold before the appraisal were made, and not replaced, naturally the decrease in value would be reflected in the appraisal. If all the property had been sold, it would have a still greater effect on the appraisal, because no appraisal would be necessary.

To wind up this part of the discussion Mr. Alvord says:

"To state it in another way: a utility company plant is not as valuable to the public without a reserve fund for replacement as it is with such a fund intact and on hand and promptly available".

This is not stating it in another way, but is an entirely different proposition. The reserve fund is a matter of finance. The cars might not be purchasable for immediate delivery, but this by no means shows that money for replacements could not be obtained simply because there was not cash enough on hand. Such a case is almost unbelievable, provided the owner enjoyed the ordinary good credit of public service corporations. Again, it is a question of service, and the public is not interested in the financing of the replacements provided the amounts thus expended do not add to the capital burden.

Under the head of "Outside Investment of Depreciation Funds", Mr. Alvord objects to investing the depreciation reserve in betterments which might give 7 or 8%, instead of the guaranteed 3½ to 4 per cent. He refers to "the general risk incident to the enterprise". As all the capital invested is subject to this risk, there is no good in splitting hairs about this particular part of the investment; but Mr. Alvord thinks that it works an injustice to the public if the owner gets a return on these betterments. If the return has been allowed for in the amount annually to be set aside, it does not. The returns are in lieu of the interest otherwise allowed by the banker who holds the depreciation fund, and these returns are required to bring the reserve up to the required amount. As to the extra rate of earning, there

Mr. Humphreys.

can be no injury to the public if the property prospers because of this or any other saving. Also, the speaker imagines that Mr. Alvord has failed to appreciate the fact that, as a rule, extensions thus made do not pay a high return at the start and are frequently made in advance of a paying demand for the service.

The speaker, as a manager, has had to face this problem in not less than fifty cities in the United States.

Under the head of "Present Practice" Mr. Alvord says:

"The rate commissions have not yet discussed this question [that of deducting a 'theoretical depreciation fund'], nor has it been effectively presented to them, but it is believed that, when discussed, it will be along lines which are here indicated."

Believed by whom? The speaker quite disagrees as to the correctness of the statement. He can hardly think of any question which has been more discussed in the cases of which he knows. He also ventures to believe that the questions involved have been "effectively presented". The statements have not always been understood, for those to whom the statements and arguments were addressed were in some cases, through lack of training and lack of experience in the several lines of construction and administration, incapable of understanding the matter presented.

Under the head of "Should a Sinking Fund Earn Full Return", Mr. Alvord says: "We will have to await with patience the conclusions of the older commissions which are giving this matter study". Again, the speaker completely disagrees with him. It is not for us to "await with patience", or with impatience, the conclusions of the older commissions, or the younger commissions, on any point. It is for us to go ahead with open minds to determine what we believe is fair and honest to the public and public utilities, and to do our best to educate the public and the commissions. If they are right and we are wrong, it is for us to acknowledge the fact; it is for them to do the same. It by no means follows that we are to accept as correct the rulings of the commissions simply because we have to govern ourselves thereby until these decisions are reversed. Even the Supreme Court of the United States is not infallible.

The speaker also objects to the reference to the "older commissions", as if they of necessity were most likely to give just decisions. That does not follow. There may be an old commission with a new personnel, and "the last state may be worse than the first".

Under the head of "Depreciation Accounts", Mr. Alvord indicates that in his opinion the cost of depreciation should be estimated liberally. He says, "Some allowance must be made for the unknown". Also, "From time to time adjustments will have to be made to correct for errors in judgment as to future life". This is quite true; but the unknown has not happened when the rate-making appraisal is

Mr. Humphreys.

made, and if no "adjustments * * * to correct for errors in judgment" have been made, how about deducting from cost new the full amount thus accumulated in the reserve?

In the speaker's experience the so-called experts testifying for the people deduct the depreciation according to an assumed "average life", and they do not worry about the "unknown" or "errors in judgment". They are so used to dealing both in the unknown and errors in judgment that they have long since ceased to worry.

On page 2060* Mr. Alvord says:

"When renewals are made, the depreciation account should be debited with the outside capital replaced in the plant by the owner, and credited by the cost of the improvement."

Is this one transaction which is referred to? Is it a replacement? If so, is it an improvement? Of course, a replacement may include in part the element of improvement, but this hardly seems to be what is intended. To what account is "the cost of the improvement" to be credited?

The speaker does not find this a self-explanatory direction for a journal entry, and would suggest that it be rewritten.

Now, as to the several items of the summary:

1.—This is incomplete.

2.—The speaker disagrees with this, absolutely.

3.—"All the facts of the past are" not known. The sinking fund is not the most accurate method of computing depreciation. The depreciation has to be estimated before the sinking fund can be computed.

4.—This is quite correct, and furnishes an answer and contradiction to much that is in the paper.

5.—The reference to "private gain" is not clear. If the speaker understands the statement, he considers it an unfair proposition.

In his concluding words, the author says: "all the principles which it is endeavored herein to reason out are not yet generally accepted".

The speaker is glad to be able to agree with Mr. Alvord here; but must go farther and express the hope that most of these "principles" never will be "generally accepted". They cannot be accepted without working confiscation in some degree.

In conclusion the speaker begs to refer to a paper recently written by him which discusses at length most of the questions raised by Mr. Alvord. This paper is entitled "Depreciation, Estimated and Actual." It was presented in June, 1913, before the Institution of Gas Engineers of Great Britain, and has been reprinted in many of the technical journals of the United States, and also in pamphlet form.

* *Proceedings*, Am. Soc. C. E., for November, 1913.

Mr. Humphreys.

In this paper the speaker supports the proposition that no deduction should be made for depreciation if the property has been adequately maintained, and particularly that no deduction should be made on account of aging of the plant. He draws the line sharply between estimated accruing depreciation and actual present depreciation, the latter as found by expert examination at the time. He also shows that in not a few cases there is no need for any estimated depreciation because the current final renewals make a fairly uniform annual charge, and this applies to properties as a whole, and in many more cases to parts of properties, so that those parts can be eliminated from the estimate of accruing depreciation.

Mr. Floy.

HENRY FLOY, ESQ.—Without discussing in detail the points made by Mr. Alvord, some of which are well taken, the paper, as a whole, is wrong in its conclusion and unfair both to the utilities and the public.

The author bases his paper on two assumptions—which he does not attempt to prove—both of which are false:

First.—That both newly originated and long established utilities must be treated alike.

Second.—That a depreciation reserve fund is a necessity.

Before undertaking an intelligent discussion of this subject, there must be drawn a sharp line of demarcation as to whether the valuation being considered is that relating to an existing and long established corporation, or one which has originated under public service regulation. The same rules may not fairly be applied equally to utility corporations so differently originated.

In a case of property constructed and put into operation before the creation of regulating commissions, the investors, with the consent of municipal, State, or Federal authorities and the sanction of the public at large, were allowed to do certain things which are no longer permitted under utility regulation. Where a corporation is created and the money of the owners is invested, after notice, under conditions prescribed in advance by regulating bodies, there can be no fair or honest objection to the insistence on accumulation of depreciation funds out of revenue and the use of such funds in any reasonable way, but they cannot necessarily be used as a measure of the value of the property on which rates are to be fixed. With respect to corporations that have been in existence for a considerable period of time without commission regulation, and have been following certain generally accepted principles with the consent, more or less definite, of public authorities, the speaker takes emphatic exception to the proposition advanced by the author, that value for rate-fixing purposes must be determined by deducting the amount of a computed but not accumulated reserve fund from the cost of reproduction new. The arguments presented in the paper may be reasonable when applied to some

Mr. Floy. newly organized corporations, but they are unfair as applied to most existing corporations. The point to be made clear is that no *ex-post-facto* rulings should be attempted by commissions or countenanced by such organizations as the American Society of Civil Engineers, simply because no reserve fund is in hand. Who shall say that, because utilities had not accumulated reserve funds before public regulation was instituted, therefore, the corporations shall now be deprived of a part of their property. In determining rates where the public and corporations have consented to the existence of a certain thing in the past that is not legally or criminally wrong, and about which there still exists honest differences of opinion, it is not fair or right, in making rulings for the future, to attempt to apply such rulings to the past at the sacrifice of investment or the jeopardy of income. It is on this point—the difference between a corporation already in existence and one originated under new laws—that the mistakes have been made in the rulings of commissioners who, for the most part, inexperienced in utility corporation affairs, have attempted to apply theoretically perfected methods which are largely the result of development and experience. It is the old truth, that the same medicine will make some men well and others ill.

That the so-called, though misnamed, present value is not determined by the cost new less the amount of depreciation or reserve fund is indicated by the fact that a fund accumulating for a period of years, based on the original investment, would probably result in too small deduction from the reproduction cost new in case of investments which have enormously increased in value, and too great deduction in the case of those which have largely decreased in value.

In the second instance it may certainly be questioned whether there is any necessity for the accumulation of a reserve fund for the purpose of ultimately returning to the investor full value of his property, except in a case of limited franchises or where the lives of utilities are definitely determined. Although in most cases a moderate reserve fund should be kept in hand for contingencies, it is a fact, as has been argued for some years by the speaker, that there are utilities which do not require the accumulation of any depreciation reserve funds whatsoever. A corporation which has its property widely distributed, of various characters, with single units of relatively small value, may not require any depreciation reserve because the deterioration of property—after the first few years of operation—is taking place at an approximately uniform rate per annum, and, therefore, all depreciation becomes wear and tear and is taken care of as a part of the annual operating expense; as an example the Third Avenue Street Railway Company, of New York City, may be cited. This property consists of nearly 300 miles of surface track, partly overhead and partly underground trolley, with rolling stock to correspond of all

sizes and types, as well as storage battery cars, underground conduits, cables, overhead transmission systems, car barns, sub-stations, generating station, real estate, and other property extending from the lower end of the Island of Manhattan up to and through the Bronx and the County of Westchester, so that the exhaustion of any physical property, as far as can be anticipated, will not result in unduly increasing operating expenses for its replacement, or affecting net income, or in any way jeopardizing service or charges to the public. Despite the orders of the Public Service Commission to do so, the Third Avenue Company accumulates no depreciation fund, and yet is operating most successfully. Mr. Floy.

Why, then, should Mr. Alvord argue that this company should have on hand a reserve fund equal to 15 or 20% net value of its property, say, from $9 000 000 to $15 000 000, for which the corporation has no use, except to be allowed to earn fair return on this property under his theory.

On page 2055,* Mr. Alvord says, "a public utility owner, under such circumstances, is tempted to let his plant run down, and withdraw from the property the funds necessary for its renewal from time to time, and use such funds for his other gainful purposes." Except under abnormal conditions, this statement is not in accordance with the facts. Valuations of a large number of utility properties of different kinds, made by a host of independent and separate appraisers, result in showing that the average condition of these properties is between 80 and 90% of reproduction value after deducting the amount of depreciation, as determined by methods suggested by Mr. Alvord, or the straight-line method of calculating depreciation which shows even a smaller present value than Mr. Alvord's method. Consequently, it may be stated, without fear of contradiction, that the condition of the average utility plant is not run down, whether or not reserve funds are maintained. Moreover, utility regulation provides for proper maintenance and service, and this can be enforced and secured even to the exclusion of dividends. Take the case of a corporation which has issued only stock, and has no bonds or mortgage indebtedness outstanding—as is not unusual, particularly in New England—in such a case, the entire interest of the stockholders is a guaranty of good service. Why, then, must the public be further protected by an unwieldy and useless reserve fund, which is of no service to the corporation, except to permit it to earn on the full value of the property?

CLINTON S. BURNS, M. AM. SOC. C. E. (by letter).—The question as to whether or not depreciation should be deducted from the cost new of a property in finding the value for rate-making purposes where the reproduction method is adopted as a basis of value, is one that has Mr. Burns.

Proceedings, Am. Soc. C. E., November, 1913.

Mr. Burns.

often suggested itself to the writer, but not until recently has he undertaken to make a comprehensive analysis of the subject with regard to the equity of the points involved. Considering the case of the most simple proposition, as cited by the author, where the composite life of an entire plant has been estimated, at the end of which the plant would be subject to entire renewal; that is to say, the original investment will have completely disappeared at the end of this estimated life, the following analysis suggests itself:

First, let it be understood that the obligation to renew the property, or any portion thereof, is a liability of the public utility company, and if the company has not the cash in hand with which to meet this liability, it must assume the burden of financing the necessary renewals whenever the necessity may arise, and as far as the public is concerned, it is immaterial whether it chooses to provide in advance for the financing of renewals by setting aside its annual accretions to the depreciation fund, or, whether it chooses to make other uses of these funds and then re-finance the renewals when the necessity arises—provided, however, that it is strong enough to accomplish such re-financing promptly when called on to do so. Furthermore, it is now conceded by all authorities that the obligation to renew the property, or, in other words, to make good the depreciation, is very properly transferred to the public (the rate-payers). This is expressed in substance by the Supreme Court of the United States in the Knoxville case in the following words:

"The Company is not bound to see its property gradually waste without making provision out of the earnings for its replacement. It is entitled to see that from the earnings the value of the property involved is kept unimpaired, so that at the end of any given term of years the original investment remains as it was at the beginning."

This language clearly defines the underlying principles which should govern an analysis of depreciation. Depreciation is an obligation to be met by the rate-payers—the public—at the time when renewals become necessary. Stating the problem in its simplest form, freed from all legal entanglements, and considering only the equity in the case, the following analysis results:

An investor, on entering the public utility business, dedicates his property to the public use, and, in return, the public obligates itself to pay a reasonable rate of return for the use of the property and to restore to the owner the value of any portion of it consumed or wasted in the public service; or, in other words, the public is obligated to make good the depreciation. Suppose, now, that the utility, at the beginning of the enterprise, should accept from the public the promissory notes of all the rate-payers, payable on demand, without interest, the face value of these notes aggregating an amount equal to the reproduction cost of the property, it being stipulated that the payments

would be demanded only as required for the renewal of totally depreciated property. If such a procedure were practical, and assuming that these notes were convertible into gold dollars on demand, at full face value, depreciation would thus be provided for; and an appraiser, called on to determine the value of the property for rate purposes, would undoubtedly recognize the injustice of deducting depreciation from the cost of reproduction in any project financed in this manner. Now, the foregoing procedure is exactly what the sinking-fund theory is, except that the investor allows these promissory notes to be paid in small annual payments, just sufficient so that if invested at compound interest, the total sum accumulated at the maturity of the notes (the expectancy of the property life), will equal their face value. The investor, therefore, in accepting depreciation on the sinking-fund basis, does not in fact, so far as its use value is concerned, have any of his available capital returned to him until the end of the life of the structure, and in order that he may receive a fair return on the value of his property, the rates must be based on the reproduction cost of the property, undiminished by depreciation. If the investor chooses to reinvest the cash on hand in the depreciation fund at any time, with the hope of securing greater returns therefor, he must assume the risk and incur the liability of returning the amount withdrawn plus its accumulations at compound interest when necessary for renewal expenditures; for example, if he is collecting depreciation on the sinking-fund basis, where 4% is considered a fair rate of interest at which to compound the fund, and he is able to withdraw the fund and invest it in extensions to the property, or elsewhere, and thus realize 8% thereon, the additional 4% is due him as compensation for the effort, risk, and worry inherent to the investment of capital, and the first 4%, being the proper rate for liquid capital, must be considered as going to restore depreciation. Mr. Burns.

The writer fails to see why any distinction should be made between the case where the sinking fund is actually kept in the bank or in trust and where it is kept merely as a book entry and has been diverted to other investments. In fact, the public, by the fundamental principles on which the sinking-fund theory is based, compels the utility owner to invest the depreciation fund somewhere, where it will draw 4% compound interest, or some predetermined rate considered proper for liquid capital; and how can it matter to the public whether it is invested in time deposits in a bank, in Government bonds drawing the necessary rate of interest, or in private venture where the owner perhaps hopes to realize 10%—and what matters it whether or not his expectations are realized? The public secures its recompense in being permitted to discharge its depreciation obligation by paying into the sinking fund the smaller annual contributions and imposing on the owner the obligation of reinvesting the fund; and the owner secures

Mr. Burns.

his reward for reinvestment if this venture proves successful, and he pays the penalty if it is a losing one.

The author states further "that the owner cannot have a return on it [the sinking fund] as a 'sinking fund' for depreciation, * * *, and at the same time have a return on it as a betterment to the plant. This would be an obvious injustice to the public." At first thought this seems plausible, but, on further consideration, is it not a fact that the contrary is the case, namely, that the public in reality owes this opportunity for reinvestment to the utility owner?

The public, having imposed on the public utility owner the necessity for reinvestment of the fund where it will earn, say, 4% interest, should in equity open the avenue of investment to him when the opportunity presents itself. To illustrate further, take the simplest case imaginable; for instance, a gravity system of water-works, where the entire property consists of $100 000 worth of wood pipe, having a life of 20 years; the utility owner dedicates this $100 000 to the public service, and, in return, the rate-payers obligate themselves to pay a reasonable return on the investment, and to preserve the property intact; or, in other words, make good the waste from usage. The rate-payers provide for the depreciation by giving their promissory notes aggregating $100 000 in face value, payable 20 years after date, without interest. The utility owner permits these notes to be paid in annual installments on a 4% sinking-fund basis, payable at the beginning of each year, or at the rate of $3 229 per annum; and it so happens that the betterments, which in this instance are for extensions to the pipe system, require the expenditure of $3 229 per year. The rate-payers, in consideration for being allowed to care for depreciation by paying the sum of $3 229 annually, permit, and, in fact, compel, the utility owner to reinvest this sum of $3 229 annually where it will earn 4% compound interest, and they also require him to invest this or some other $3 229 annually in pipe lines for extending the service to the new territory; but they pay him extra in consideration for these new extensions an amount equal to 3.229% to restore depreciation and, in addition thereto, a reasonable return on these further sums invested annually.

Two courses are open to the investor: he may leave the first $3 229 annually in a trust fund, earning 4%, in some reliable bank, and use $3 229 annually of his other resources in extensions, or, he may expend the $3 229 depreciation fund directly for extensions. In the former case he will find his situation in 20 years to be as follows:

He will have $100 000 in the trust fund with which to replace the original pipe system, and he is also in possession of $100 000 worth of extensions paid for from his outside resources. In the latter case, he will find at the end of 20 years that he has $100 000 worth of pipe requiring replacement, with no funds in trust, but he has the $100 000

in his outside resources which he may as well now spend all at once instead of at the rate of $3 229 annually, as was done in the former case. He also has the same investment in extensions or betterments as in the former case. Hence, the owner's financial situation is exactly the same at the end of 20 years regardless of which method of finance he chooses to pursue. The public is likewise in identically the same position in either case; for, had the owner left the depreciation account in trust until the $100 000 had accumulated, at the end of 20 years that sum is due the owner in exchange for his worn-out property, dedicated and consumed in the public service. Hence, the public could have no claim on the sum, nor title to any portion of it. Neither the owner of the utility nor the public being in any wise affected by the owner's withdrawal of the sinking fund for reinvestment or for extensions of the property, it would seem proper that the valuation for rate purposes should be the same in either case, no matter whether the sinking fund is left in a trust fund or used for private venture. If the amount of depreciation to be set aside annually is computed on the sinking-fund theory, it, therefore, seems that no deduction can equitably be made from reproduction cost in arriving at the proper valuation to use as the basis of rates. The rate-payers, therefore, should contribute annually $3 229 for depreciation and the reasonable rate for interest and profits to the owner, regardless of whether or not the depreciation fund is held in reserve. Mr. Burns.

The writer, therefore, can see no reason in equity for the conclusion that any injustice to the public results from allowing the owner of the utility to have return on the sinking fund for depreciation at the proper rate of interest for such depreciation accounts, and at the same time have return on it as betterment to the plant, for each betterment to the plant simply means a larger investment or larger plant on which the owner is entitled to the proper reasonable rate of return. Doubtless what the author had in mind was that it would be unjust to allow the owner to reinvest the sinking fund in betterments and receive thereon, say, 8% net return, and, at the same time, receive 4% as sinking-fund accumulation. It seems to the writer, however, that when the owner invests his sinking fund in betterments, or in private enterprise, and thereby receives 8% return, he in fact, does not receive 8%, but, on the contrary, receives only 4%, because half of this 8% return does not represent profit but simply goes to restore to him some of his property already consumed by the public in the public service.

If a community constructs a utility under municipal ownership, it is almost universally the custom to pay for such a utility by a bond issue. Now, to determine the basis of rates in such a municipal enterprise, in order that it shall be made exactly self-supporting, with no surplus, the amount of the original bond issue is always taken as

Mr. Burns. the basis on which the community must pay interest, assuming that the sinking fund with which to pay off the bonds is based on an expectancy equal to the life of the property; that is to say, if the bond issue runs for the number of years represented by the life of the property, the community must set aside a sinking fund sufficient to pay off the bonded indebtedness, and must likewise continue to pay interest on the full amount of the bond issue, regardless of the fact that the property itself is continually depreciating in value. In fact, this method of financing the enterprise is absolutely essential if the project is to be made self-sustaining. How, then, can there be any escape from the conclusion that a privately owned utility must receive its return on the same basis, for to receive less will undermine the integrity of the investment, and is, therefore, not a fair return. Of course, if the municipal bond issue is to be paid serially, then the amounts paid off from time to time would be deducted from the capital on which the public must continue to pay interest, but in order to pay these bonds serially, the annual levy or contribution for sinking-fund purposes must be largely in excess of the amount necessary for the application of the sinking-fund theory. It would seem, therefore, that the proper deduction to make from reproduction cost is simply the amount by which the actual depreciation allowance exceeds the theoretical accumulation in a sinking-fund account, computed on the age and life of the property. If depreciation is figured on the sinking-fund basis only, therefore, no deduction should be made from reproduction cost.

The Public Utilities Act of California, in effect March 23d, 1913, provides, in Section 49, that:

"The Commission shall have power, after hearing, to require any or all public utilities to carry a proper and adequate depreciation account in accordance with such rules, regulations and forms of account as the Commission may prescribe. The Commission may, from time to time, ascertain and determine and by order fix the proper and adequate rates of depreciation of the several classes of property of each public utility. Each public utility shall conform its depreciation accounts to the rates so ascertained, determined and fixed, and shall set aside the moneys so provided for out of earnings and carry the same in a depreciation fund and expend such fund only for such purposes and under such rules and regulations, both as to original expenditure and subsequent replacement as the Commission may prescribe. The income from the investments of moneys in such fund shall likewise be carried in such fund."

With the administration of the depreciation fund in accordance with this Section of the California Act, it would seem that such fund must be kept separate and set aside, and as far as the owner of the utility is concerned, he has no discretion whatever over its disbursement, and he cannot withdraw such fund for any purpose other than for the replacement of depreciated property. Therefore, depreciation

cannot equitably be deducted from the cost of reproduction in California rate cases when that method is used to determine the value of the property. Mr. Burns.

Section 47 of the Public Utilities Act of Idaho, and also Section 79 of the Public Utilities Act of Missouri, use almost exactly the same language as the California Section already quoted. This indicates the tendency in recent legislation to require public utility companies to set aside sinking-fund accounts, or, in other words, it takes these accounts out of the hands of the public utility owners and leaves them largely under the control of the public through its representatives, the public service commissions. There can be no objection to leaving the collection and disbursement of the sinking fund entirely under public control through proper utility commissions, and, in fact, it is highly desirable that such should be the case, but it is important that the commission should study carefully the conditions surrounding each property in order that the amount of depreciation collected from the rate-payers, and thus set aside, shall be adequate and equitable under all the circumstances.

Contingent depreciation should receive special consideration in each case, its amount depending on the nature of the property. Contingent depreciation is the sum that should be provided from earnings to meet unusual or unexpected replacements which become necessary from time to time in the experience of every public utility, such, for example, as damage from floods, destruction of property by earthquake or ice gorge, failure of water supply, and many similar experiences. Depreciation by obsolescence or changes in the art should also be fully covered by the allowance for contingent depreciation. In fact, contingent depreciation may be defined as the sum that should be provided for insurance against such contingencies as cannot be covered by any class of commercial insurance. This raises an important question: Is the sinking-fund method of computing the depreciation fair to the owner of a utility in a rate-regulation investigation? Evidently not, unless the rates are based on the cost of reproduction undiminished by depreciation, but, under the usual procedure in a rate investigation, it is extremely difficult, if not utterly impossible, to receive consideration for the full reproduction value of a public utility, and would it not be more practical, therefore, to adopt some system of accounting depreciation that will secure equity to both parties when considered in conjunction with a proper rate of return on the remaining expectancy of the property? Perhaps this can be understood more clearly by considering the property as passing through a series of successive ownerships. It cannot be denied that the owner may sell the property at any time and retain the accumulated depreciation fund. This fund is due him, for, if he sells the property at its fair value, computed

Mr. Burns.

on the sinking-fund basis, he must retain the depreciation fund in order to recover the full amount of his investment.

Consider again the case in its simplest form, the gravity system of water-works previously cited, and, for the purpose of simplicity, assume that no extensions or betterments are required throughout the 20 years' life of the property, and that no elements of appreciation in value accrue to affect any portion of the works. The first owner should receive from the rate-payers the sum of $3 229 for depreciation and a reasonable return on his investment of $100 000. He sells the property at the end of the first year at its value, computed on the sinking-fund basis, namely, $96 771. The second owner should receive from the rate-payers for depreciation the sum of 3.475% of his investment of $96 771, or $3 362.79—this being computed on the basis of the remaining life of the property, 19 years—and, in addition thereto, he should receive a reasonable rate of return on the reduced capital account, $96 771. Now, if such a rate is equitable to each of the successive owners of the property, it must be equally fair to the public and to the owner throughout the life of the property, if the same ownership continues throughout the entire period. For the purpose of illustration, Table 3 is submitted, computed on the basis of 4% compound interest on the depreciation fund, 8% for interest and profit on the capital investment, and a variable allowance for contingent depreciation, starting at 2% of the capital account and increasing as the property becomes older, the amount of increase being such as to preserve a constant total contribution from the rate-payers. It is desirable, from the point of public expediency, that rates be not fluctuating, and this may be accomplished by the variable contingent depreciation, based on an amount that shall represent, as nearly as can be predetermined, the facts in each case under consideration.

An examination of the column in Table 3 headed "Contingent Depreciation", shows that the variation in contingent depreciation from year to year is not great, under this system of accounting, and represents very closely what may be reasonably expected, increasing gradually with the age of the property. The contingent depreciation is not a cumulative fund, but, on the contrary, represents the amount actually spent from time to time in replacing obsolete or abandoned property and in repairing damage from unexpected or unusual causes. If properly proportioned, such a fund will fluctuate between surplus and deficit, but will maintain a general average near the zero line. The actual figures used in Table 3 are, perhaps, not appropriate for a property of this nature, but are submitted simply to illustrate a principle and without reference to the adequacy, or otherwise, as this can be determined only by a study of all the circumstances surrounding each particular property. The table is based on annual contributions to a sinking fund at the beginning of each year, although many

authorities prefer using the tables computed for the end of the year. Rates are usually collected quarterly or monthly and, therefore, as a matter of fact, it would more nearly accord with correct theory to use tables computed for annual contributions in the mid-year, if such tables were at hand. However, this difference is not sufficient to cause material error in any event. Mr. Burns.

TABLE 3.

Owner.	Capital invested.	Depreciation.		Interest and profit. 8 %.	Contingent depreciation.	Annual cost to rate-payers.
		Rate. Per cent.	Amount.			
1st.....	$100 000	3.229	$3 229	$8 000	$2 000	$13 229
2d.....	96 771	3.475	3 363	7 742	2 124	13 229
3d.....	93 408	3.749	3 502	7 473	2 254	13 229
4th.....	89 906	4.058	3 648	7 193	2 388	13 229
5th.....	86 258	4.406	3 801	6 901	2 527	13 229
6th.....	82 457	4.802	3 960	6 597	2 672	13 229
7th.....	78 497	5.257	4 127	6 280	2 822	13 229
8th.....	74 370	5.783	4 301	5 950	2 978	13 229
9th.....	70 069	6.399	4 484	5 606	3 139	13 229
10th.....	65 585	7.130	4 676	5 247	3 306	13 229
11th.....	60 909	8.009	4 878	4 873	3 478	13 229
12th.....	56 031	9.086	5 091	4 482	3 656	13 229
13th.....	50 940	10.435	5 316	4 075	3 838	13 229
14th.....	45 264	12.174	5 554	3 621	4 054	13 229
15th.....	40 070	14.496	5 809	3 206	4 214	13 229
16th.....	34 261	17.753	6 082	2 741	4 406	13 229
17th.....	28 179	22.643	6 381	2 254	4 594	13 229
18th.....	21 798	30.803	6 714	1 744	4 771	13 229
19th.....	15 084	47.134	7 110	1 207	4 912	13 229
20th.....	7 974	96.154	7 667	638	4 924	13 229

Unfortunately, in actual practice, the problem is never so simple as the gravity water-works system used in this illustration. Public utility enterprises are, from the very necessity of the case, almost continuously extended from year to year, so that the average age of a property of this nature never even remotely approaches that of its oldest parts.

If the theory outlined herein is accepted as a correct method of computing depreciation, its practical application would be somewhat as follows:

The appraiser would determine the composite life of the utility under consideration, which, for illustration, in the case of a water-works system, in some particular case might be found to be 60 years. The average age of the entire property, computed in like manner, might be found, for example, to be 20 years. The rate to be used in determining the amount of ordinary depreciation therefor would be based on an expectancy of 40 years. On a 3% sinking-fund basis, this would be 1.288%—this percentage to be applied to the remaining capital determined by deducting the sinking-fund accumulation of 20 years from the cost of reproduction of the property. The proper

Mr. Burns. additional amount to be allowed for contingent depreciation, of course, should be determined by the particular circumstances in the case. It would be more precise to compute the result separately for each group of items having the same age and estimated life; but such a procedure would, perhaps, be impractical in most cases, owing to its difficulty of application.

Mr. Knox. STUART K. KNOX, M. AM. SOC. C. E. (by letter).—Mr. Alvord's paper, dealing with "the general relation of depreciation and its effects on the fair return of a utility property," will have justified itself if it does no more than precipitate the extended discussion of this interesting and intricate subject, concerning which ideas are at present so confused and conflicting. In this, it appears to the writer, will lie its chief, if not its only, value.

As the author implies, there exists at the present time a wide diversity of opinion among engineers, lawyers, special masters, commissions, and Courts having to do with valuations for rate-making purposes, with regard to the fundamental question of the value on which fair rates should be predicated.

Among those who have sought to sustain the reproduction-cost-new theory may be mentioned the special master,* *re* Columbus Railway and Light Company *vs.* City of Columbus, Ohio, 1906; the Wisconsin Railroad Commission,† *re* City of Whitewater *v.* Whitewater Electric Light Company, decided December 16th, 1910; Massachusetts Joint Board,‡ Massachusetts Appraisal of the New York, New Haven, and Hartford Railroad, 1911; C. E. Grunsky,§ M. Am. Soc. C. E., in his paper entitled "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates", to which paper the author refers; and Alexander C. Humphreys, M. Am. Soc. C. E.,|| President of the Stevens Institute of Technology, in his paper entitled "Depreciation: Estimated and Actual", presented before the Institution of Gas Engineers of Great Britain, 1913.

The contrary view, to the effect that fair rates should be adjusted to yield a fair return only on depreciated reproduction-cost, has been upheld by the Oklahoma Supreme Court,¶ *re* Pioneer Telephone and Telegraph Company *v.* Westenhaver, decided January 10th, 1911; by the New York Public Service Commission for the First District,** *re* Metropolitan Street Railway Reorganization, decided February 27th, 1912; and by the United States Supreme Court.

Mr. Alvord's ideas on the subject are summarized in his first and second "conclusions," as follows:

** *Loc. cit.*, p. 376.

Mr. Knox.

"1st.—That if a sinking fund or a reserve fund for depreciation is actually kept in the bank or in trust as part of the property, it should, if properly computed and accurately kept, receive the same rate of fair return as the remainder of the property 'used and useful for the public'.

"2d.—That if these funds are for any reason detached or withdrawn from the property and used by the owner elsewhere, or in private gain, or even as new capital invested in the plant itself, he cannot hope, as a matter of proper protection to the public, to receive return on a reserve fund which is not actually in hand and at the same time use such funds for other personal gain."

The writer is not prepared to admit the truth of either of these propositions without material qualification, and in the following discussion will seek to show:

(*a*) That the disposition made of the depreciation reserves has theoretically no bearing whatever on the question of value on which the owner of a utility property is entitled to earn a fair return.

(*b*) That the question of value on which an owner is entitled to earn a fair return depends solely on whether the depreciation reserve provided has been or is to be just "adequate", "excessive" in amount, or "inadequate" for the purpose intended.

He will endeavor to demonstrate that when the depreciation reserves, which have been and are to be provided, are just "adequate" for the purpose intended, the owner must, if he is to be protected against the impairment of his capital or of its earning power, be permitted to earn, in addition to operating expenses and this "adequate" depreciation reserve, a fair return on reproduction-cost-new.

That when the depreciation reserves, which are to be provided, are "excessive", so as virtually to effect a refund to the owner of a portion of his original investment, together with its full earning power, rates may be equitably adjusted to yield a fair return on a value less than reproduction-cost-new, the measure of the reduction being the total amount of the capital so refunded.

That when the chosen method of providing for future depreciation is such as virtually to effect a progressive refund, free and clear, of a portion of the owner's original investment, a corresponding progressive decrease in the value on which he is allowed to earn a fair return may be equitably made.

That when the depreciation reserves which have been provided are "excessive," so as virtually to have effected a refund of a portion of the owner's original capital, rates may be equitably adjusted to yield a fair return on a value less than reproduction-cost-new only if no change in ownership has taken place.

That when the depreciation reserves which have been provided are "inadequate", so that an actual impairment in capital has taken place,

Mr. Knox.

we should, to be consistent, and provided full ownership is still retained by the owner who suffered the loss, permit the adjustment of rates to yield a fair return on a value greater than reproduction-cost-new until this loss has been recouped.

That rates may be equitably adjusted to yield a fair return on depreciated reproduction cost, only if the virtual refund of capital, resulting from "excessive" past or prospective depreciation reserves, just equals the accrued depreciation on the property on the date of the valuation for rate-making purposes.

As a preliminary to the intelligent discussion of the preceding propositions, it is essential first to define exactly what is meant by "adequate", "excessive", and "inadequate" depreciation reserves, and by the expressions "accrued depreciation" and "depreciated reproduction cost".

By "adequate" depreciation reserve is meant the annuity or percentage of reproduction-cost-new which, if set aside in the bank or in trust from the beginning of operation, at the rate of interest, say 4%, on which the fund payments are predicated, will, with all interest accretions, amortize a sum which, at the termination of the useful life of each element of the property, will just suffice to replace it and no more.

By "excessive" depreciation reserve the writer means an annuity greater in amount, and by "inadequate" depreciation reserve an annuity less in amount than the above.

By "accrued depreciation" at any period of the life of a property, is meant the amount which an "adequate" depreciation reserve would have amortized had it been set aside each year from the beginning of operation.

By "depreciated reproduction cost", is meant the reproduction-cost-new less the "accrued depreciation" so determined.

By the "useful life" of any element of property, is meant its age plus the remaining life expectancy of the element.

In explanation and justification of the foregoing definitions, it may be well to digress at this point to the extent of acknowledging a full realization of the fact that any estimate of accrued or prospective depreciation is at best a guess. There are, however, intelligent guesses and unintelligent guesses, and there are intelligent ways of guessing and unintelligent ways of guessing. One unintelligent way of guessing the accrued depreciation on a pumping engine, for example, is to sit in the office and compute it, starting with the assumption that the normal life expectancy of a new unit of the type considered is 20 years, and that the age of the particular unit under consideration is, say, 10 years. The unit may have been in continuous service from the date of its installation, or it may have been used largely as a spare. It may have been operated 24 hours per day, or only 1 or 2 hours per

day. It may or may not have had intelligent care, and it may or may not be well adapted to the service, well designed, and of modern type. No intelligent guess of accrued or prospective depreciation can be made without a visual field inspection of the element to be appraised. Mr. Knox.

Whatever be the age of a unit, or structure, the present value of which it is desired to ascertain, the uncertain element affecting this value which may be guessed most accurately by an expert is its remaining life expectancy. In the light of the history and probable future of the plant, of the community which it serves, and of the arts, this, after an examination of the unit or structure, may be gauged as closely as any other probability affecting the future of the property. Then, if the guess proves accurate, the "useful life" of the element becomes its age plus its life expectancy on the date of the appraisal; and an "adequate" allowance to cover annual depreciation is the annuity, which, had it been paid into a fund each year since the installation or construction of the unit or structure, would have amortized a sum sufficient to reproduce it at the end of this "useful life". Under these conditions the "accrued depreciation" on the date of the appraisal may fairly be estimated as the amount which such an annuity would have accumulated between the date of installation and the date of the appraisal, and its fair market value or depreciated reproduction-cost at the date of appraisal may fairly be assumed to be its reproduction-cost-new less the accrued depreciation so found. Fair market value under these circumstances would of course be defined to be the value as established between a seller who was willing but not compelled to sell and a buyer who was willing but not compelled to buy.

In all that follows, it will be assumed that the guesses as to life expectancy and hence of proper or "adequate" depreciation reserves are accurate ones.

To come to the discussion of Mr. Alvord's conclusions, it is undoubtedly true as the author states that "there must be in this, as in all other questions relating to this difficult subject of valuation, a just and equitable relation between the public and the public utility owners, which is founded on rational analysis and common sense." In seeking out this relation much is gained in the way of clarity by confining ourselves at first to the consideration of simple examples. We are thus able to eliminate the many complicating, confusing, and often entirely irrelevant considerations which usually cloud and obscure the vital principles involved, when the question is studied in the light of complex cases such as commonly come before the Courts. Although it is no doubt true, as the author implies, that conclusions deduced from the consideration of simple examples will not always admit of indefinite extension to cover the complex cases met in actual practice, we seem at least to be on safe ground in assuming, as a point of departure, that a conclusion which will not withstand the most searching

Mr. Knox.

analysis, when viewed in the light of its application to a simple practical example, cannot be the basic principle or relation which we are seeking. At any rate, let us grant the truth of this proposition for the moment, and observe the result of applying such a test to the conclusions reached by Mr. Alvord, beginning with his first conclusion, "that if a sinking fund or a reserve fund for depreciation is actually kept in the bank or in trust as part of the property, it should, if properly computed and accurately kept, receive the same rate of fair return as the remainder of the property 'used and useful for the public'."

If by a "properly computed and accurately kept" sinking fund, Mr. Alvord means an "adequate" depreciation reserve, as defined in a preceding paragraph of this discussion, the logic of this conclusion appears to be unassailable.

Consider, for example, a water-works plant, consisting solely of a pipe line 10 miles long. The owner of this property, we will say, buys water at wholesale at one end of the pipe line, and sells it at wholesale at the other end. The writer has in mind a private water company the property of which is substantially as described. Assume that the reproduction-cost-new of the pipe is $1 000 000, its useful life 50 years, and its scrap value nothing. No part of the line will require replacement during its 50-year life, and the pipe may be maintained in good serviceable condition throughout the entire period by making such ordinary repairs as may be properly charged to operating expense. Neglecting the fact that the creation of a sinking fund must lag one year behind the commencement of operation, the proper annual reserve to cover depreciation, estimated on a 4% sinking-fund basis, is $6 550, which amount the owner places in bank each year at 4% compound interest.

In the construction of this pipe line, the owner converted $1 000 000 of money into physical plant. As the pipe ages, it depreciates in value, and if the guess as to its useful life (50 years) proves correct, the amount of this depreciation is, as nearly as may be, represented at any time by the accumulation in the sinking fund or reserve fund for depreciation. The process may be regarded as the gradual re-conversion of plant value into cash, until at the end of the pipe's useful life the owner has all cash and no pipe line, at which time the money accumulated is again converted into physical plant through the taking over of a new pipe line which the owner has caused to be constructed. At any intermediate period of the life of the pipe, the owner's capital is represented partly by the depreciated value of the line, and partly by the depreciation reserve. The sum of the two may be considered as representing at any time the reproduction-cost-new. A purchaser can at any time afford to pay for the pipe line and depreciation fund together, a sum equal to the pipe's repro-

duction-cost-new, for by continuing the depreciation reserve in bank, and adding the proper annual payments, as these are earned, he will have available at the termination of the useful life of the property a sum equal to his original investment and to the pipe's reproduction-cost-new. This is equivalent to saying that a purchaser can at any time afford to pay for the pipe line alone a sum equal to its reproduction-cost-new less the accumulations in the sinking fund, or its depreciated reproduction cost. Mr. Knox.

Now, as all interest accretions, if the annual depreciation reserve is a proper or "adequate" reserve computed on the sinking-fund basis, must be credited to the fund, the owner enjoys no income therefrom, and, therefore, should be allowed to earn a fair return on the depreciated physical value plus the depreciation reserve, or on the reproduction-cost-new. To assert the contrary is to assert that the owner must, in spite of everything he can do, suffer a financial loss through impairment of the earning power of the capital which he has invested.

Let us now examine Mr. Alvord's second conclusion:

"That if these funds [adequate depreciation reserves] are for any reason detached or withdrawn from the property and used by the owner elsewhere, or in private gain, or even as new capital invested in the plant itself, he cannot hope, as a matter of proper protection to the public, to receive return on a reserve fund which is not actually in hand and at the same time use such funds for other personal gain."

Suppose that the owner of the pipe line operates his plant in exactly the same way as described, except that instead of actually placing $6 550 in bank or in trust each year as part of the property, he invests this amount in other ways, or even places it in a safe deposit vault or squanders it. Mr. Alvord concludes that under these circumstances rates may be equitably adjusted to yield a fair return only on the depreciated physical value of the pipe instead of on its reproduction-cost-new. This means that unless the annual depreciation reserves are correspondingly increased above the "adequate" amount previously estimated, a sliding scale of rates must be introduced, such that the amount available for interest in the tenth year of operation, after deducting operating expenses and depreciation reserve, will be approximately 92%, in the fortieth year approximately 38%, etc.. of its amount in the first year of operation. As the service is now by hypothesis exactly the same as in the case where the depreciation reserve was actually deposited in bank as part of the property, the water consumer will evidently gain in reduced rates by the owner's failure to establish an actual depreciation reserve. It is equally evident that the consumer cannot gain unless at the same time the owner loses an equal amount. Let us pursue the illustration further.

Suppose that the owner, in the tenth year of operation, becomes alarmed at the dwindling profits on his water transportation business,

Mr. Knox. and begins to busy himself in devising a plan for restoring rates to the point where they will yield the same return on his capital as in the first year. He estimates that if he had from the outset maintained a depreciation fund in the bank at 4%, the accumulations in this fund would at the end of the tenth year have amounted to $78 760.56. He, therefore, sells at par from his private means seventy-nine $1 000 municipal bonds drawing 4% interest, or he sells, we will say, an apartment house valued at $78 760.56, which has been yielding him a net return of 4% per annum. He deposits the proceeds, $78 760.56, in the bank at the beginning of the eleventh year and christens it a depreciation fund. He has not lost a dollar by this transaction. The depreciation fund is his property in the same way that the house was his property. The interest yield is the same. He has simply performed the familiar operation of taking a sum of money out of one pocket and placing it in another, and yet, as a result of this simple shifting of assets, he has placed himself in a position where he may equitably charge his customer, the water consumer, we will say, an additional $10 per 1 000 000 gal. for exactly the same quantity and quality of water, delivered under exactly the same pressure as before the depreciation fund was created. Could anything be more absurd?

Mr. Alvord speaks of the use of the depreciation reserves, by the owner, "for other personal gain". It is, of course, apparent that when these reserves are proper or "adequate" reserves computed on the sinking-fund basis, it is entirely beyond the power of the owner to use them so as to yield "a private gain", unless he invests them in a way to yield a return greater than that which they would have earned if placed in the bank or in trust at the rate of interest on which the sinking or depreciation fund payments were computed.

If correctly computed on the sinking-fund basis, the sum of the annual reserves will, by hypothesis, produce an amount sufficient to provide for future replacements, only if credited with all interest accretions resulting from their conservative investment. The source of these interest accretions is immaterial. The funds are equally unproductive, as far as concerns their power to yield a "private gain" to the owner, whether they be placed in bank at 4% interest, invested in high-grade municipal bonds at 4% interest, or invested in other ways. If the owner is fortunate enough to invest them in a way to yield a return greater than they would have earned if placed in a bank or in trust, his "private gain" is represented, not by the total yield of the funds so invested, but only by the excess of this yield over and above what they would have earned if placed in the bank or in trust. To obtain this excess yield or "private gain", the owner performs services and assumes risks for which he is entitled to compensation represented by the excess yield. He has, in fact, entered the banking business and is as much entitled to a fair profit on this banking business

as he is on his water-works business. In his capacity of water-works manager, he deposits with himself, in his capacity of banker, the depreciation reserves on which he pays 4% compound interest. When the time arrives, he must return these sums with accumulated interest, the same as any other banker would be obliged to do. In the meantime he is entitled to invest them conservatively in such a way that they will yield enough more than 4% to compensate him for performing the services and assuming the responsibilities and risks which attend the banking business. Mr. Knox.

There are bankers and trust companies, many of them, that actually own and operate water companies. Is it to be presumed that these banking institutions, to avoid being "fined," must invest their depreciation reserves with some competitor, perhaps less responsible and competent than themselves? Again, the proposition is absurd.

Theoretically, the consumer has no interest whatever in the depreciation reserves or in the disposition which is made of them. He is interested only in the quality of the service. Service is what he pays for. He pays not for the quality of service which an element of plant is capable of rendering when new, or at its absolute maximum of efficiency, but for the average service which it is capable of rendering during the period known as its "useful life," when maintained throughout this life in the highest state of efficiency which is physically possible, and replaced at its termination with a new element. In the absence of certain knowledge to the contrary, it must be presumed that the owners will so maintain and so replace the plant, regardless of whether or not an actual, tangible depreciation fund is maintained in a bank—a competitor's bank. Even when depreciation reserves have been distributed to stockholders, or lost or tied up in unfortunate investments, it must be presumed, in the absence of certain knowledge to the contrary, that the owners will provide funds as required by dividend reductions, assessments against the stock, or in extreme cases by reductions in interest.

As a practical matter, it is granted that in certain cases the owner's failure to invest depreciation reserves conservatively may react on the consumer, and that to this extent he is interested in the disposition which is made of them. It is, for example, a matter of common observation and knowledge that when an owner first becomes involved in financial difficulties there exists the temptation and tendency to maintain dividends and interest at the expense of maintenance and replacements. The prevention of this is one of the functions of the regulating power.

As long as the quality of the service is actually maintained, there can exist no logical reason why the value on which the owner of a property is entitled to earn a fair return should be variable, depending on whether or not a reserve for depreciation is maintained in the

Mr. Knox.

bank or in trust as part of the property. To penalize or "fine" an owner for failure to maintain an actual fund by adjusting rates to yield a fair return only on depreciated reproduction-cost, is to presume in advance of the fact that he will not, when required, and at his own cost, make the replacements for which depreciation reserves were provided. It is in effect to punish him in advance for an offense that it is suspected he may commit at some time in the future.

The points just made have been clearly stated by the Wisconsin Railroad Commission *re* City of Whitewater and Whitewater Electric Light Company, decided December 16th, 1910.* The Wisconsin Railroad Commission says:

"As it is a general rule that the reasonable return which a utility is allowed to earn covers the interest and depreciation on the actual investment in the plant, it becomes important to know what the investment in the plant actually is—that is, what is the value of the plant new. The fact that the property of the utility has diminished in value with use, as the inevitable result of depreciation, does not lessen the amount of the investment in the plant. To be sure, it may happen in the case of a given utility that money which should have gone to the establishment of a depreciation fund has been diverted to the stockholders, thereby apparently lessening their investment. If an amount equal to the difference between the value of the plant new, and the value in present condition is thus paid over to stockholders, it would appear, at first sight, that the value of the plant in present condition would be the basis on which interest returns should be allowed. But it must not be forgotten that at the expiration of the life of the plant if the money which should have been used to provide for depreciation has been paid to stockholders in the form of dividends or otherwise, the value of the plant will be nothing. Then, instead of the utility having a depreciation fund on which to draw to replace the plant, the owners will find it necessary to pay the cost of replacement, presumably from the money which they have received from the plant, but which should have been used to provide a depreciation fund. The investment in the plant then must, in general, be taken at the cost of the plant new, since although the investment may apparently be diminished by failure to provide for depreciation, and by the payment of this money to owners or stockholders, in reality the investment is not diminished, because of the necessity of replacing the plant, in the absence of a depreciation fund, from the property of owners or stockholders. Therefore, it appears that the question of valuation, which is of most importance in the case, is that of cost of the plant new, or the actual value of the total investment in the plant."

It is not necessary to state that a reduction, below reproduction-cost-new, of the value on which an owner is permitted to earn a fair return, may be logically justified only on the assumption that a virtual refund of a portion of the capital originally invested has taken place prior to the date of the valuation for rate-making purposes. It has

* Robert H. Whitten, "Valuation of Public Utility Properties," p. 366.

Mr. Knox.

been shown that no such refund is effected where an owner, in lieu of maintaining an actual tangible depreciation fund in the bank, invests these reserves in other ways. There are, however, ways in which such a virtual refund may occur, and it may prove interesting to examine one or two of them.

Suppose, for example, that the owner of the pipe line, previously referred to, instead of setting aside each year in addition to operating expenses and interest an "adequate" depreciation reserve of $6 550, sets aside a depreciation reserve, improperly computed on the straight-line basis, of $20 000 per year. Under these circumstances interest accretions are no longer, of necessity, credited to the fund, for the sum of the annual payments themselves, will, without interest, accumulate an amount sufficient to replace the pipe line at the end of its useful life. Whether placed in the bank as an actual tangible depreciation fund, or invested in other ways, the owner may each year draw and add to his gross earnings the income from this fund without in any way defeating the object for which it was created. However it be invested, the entire fund may now be used productively by the owner "in private gain." A portion of his original investment equal in amount to the sum of the annual depreciation reserves has in effect been refunded to the owner by the consumer. It has been refunded free and clear, together with its full earning power, and if the owner is to be prevented from receiving, at the expense of the consumer, a double interest return on the same principal, rates must be adjusted to yield a fair return not on reproduction-cost-new and not on depreciated reproduction cost, but on reproduction-cost-new less the sum of the "excessive" annual depreciation reserves. This value will be less than the depreciated reproduction cost. At certain periods during the life of the pipe, it will be materially less. At the end of the twenty-fifth year, for example, the "accrued depreciation," or the sum amortized by an "adequate" depreciation reserve of $6 550 per annum, will be only $272 803, whereas the sum of the annual depreciation reserves, without accrued interest, will be $500 000. The depreciated reproduction cost on that date will be $1 000 000 — $272 803 = $727 197, whereas the value on which the owner should be allowed to earn a fair return will be only $1 000 000 — $500 000 = $500 000, or about two-thirds of the depreciated reproduction cost.

If an owner has, during the past, set aside out of earnings an "excessive" annual depreciation reserve, or if he has, what amounts to the same thing, enjoyed excessive profits, it may appear from the preceding discussion that the ends of justice will be served by adjusting rates to yield a fair return on a value less than reproduction-cost-new. The justice of the procedure, when adopted as a retroactive or punitive measure, is, however, only apparent. The ownership of most public utility properties is constantly changing through transfers of stock,

Mr. Knox.

and reprisal would in many cases fall not on the original owners, who alone could be supposed to merit it, but on the present owners who purchased in good faith, at a fair price, and reaped no benefit from past extortions.

Suppose, for example, that at the end of the twenty-fifth year, and just prior to the date of a valuation for rate-making purposes, the pipe line, previously referred to, had been sold by the original owner, A, to the present owner, B. Suppose that A, throughout the period during which he operated the line, had extorted from the public, in addition to a fair return on his capital, improper depreciation reserves estimated on the straight-line basis, which amounts he did not transfer to B with the depreciated property. A has now placed himself beyond the reach of reprisal. He has gone out of the waterworks business, taking his unholy profits with him. He has sold his plant for its market value which, for the purposes of this discussion, may be assumed to be fairly represented by its depreciated reproduction cost at the date of sale ($727 197). He could not have sold it for more however moderate his early charges for depreciation had been. B has purchased the property in good faith and for a fair price. It might now be argued superficially that as far as B is concerned, the price paid represents his total investment, and that the adjustment of rates to yield a fair return on this purchase price will impose no hardship on him; but this is not the case. The fallacy in the reasoning, though perhaps not obvious, lies in the assumption that the money which B has paid to A for the physical property represents his total investment in plant. It does not. A has sold to B a depreciated physical property plus a liability. The liability consists in the obligation which B incurs of replacing the depreciated pipe line at the end of its useful life. To place himself in a position to meet this obligation when it matures, B must, on the date of the purchase, set aside in bank at 4% interest an amount ($272 803) equal to the accrued depreciation on the plant. If he fails to do this, he, nevertheless, automatically, by the assumption of the obligation, ties up an equal amount of his outside investments as far as concerns their power to yield him a "private gain." In any case his total investment is not represented by the sum of money paid to A, but by this amount plus the accrued depreciation. Whatever disposition he makes of the depreciation reserve, if it is only an "adequate" reserve as previously defined, B will inevitably suffer a financial loss unless allowed to earn a fair return on $1 000 000, the reproduction-cost-new. Any reduction in this value will inevitably work a great injustice by causing B to suffer for the sins of his predecessor.

B, it is true, will be protected against loss, if at the same time that rates are adjusted to yield a fair return on depreciated reproduction cost, he is allowed to set aside each year from earnings, an "exces-

sive" depreciation reserve sufficient to reproduce the depreciated plant value ($727 197) at the end of its 25 years of remaining life. It may indeed be laid down as a general rule that where past depreciation reserves with interest accretions have been adequate to take care of the accrued depreciation, and future reserves are made sufficient in themselves to amortize sums which will provide against all subsequent deterioration, rates may fairly be predicated on the depreciated reproduction cost at the date of the valuation for rate-making purposes. Mr. Knox.

Although there is one notable exception which the writer will discuss later, the adoption of this rule will usually result in difficulties and confusion in accounting, with no attendant benefits either to the consumer or to the owner. Decreasing the amount allowed for interest and at the same time allowing a corresponding increase in amounts allowed to offset depreciation is a mere juggling of figures. An annuity sufficient to amortize the depreciated value of a property at the termination of its remaining life expectancy will become an "excessive" annuity on the day the first replacement is made, and generally the depreciated reproduction cost will be modified as a result of each replacement.

On the other hand, if we neglect the fluctuations in the prices of labor and materials, reproduction-cost-new will remain an unvarying quantity as long as no additions are made to the property, and the "adequate" annual depreciation reserve, estimated in the customary way, will remain at all times a constant percentage of the unvarying reproduction-cost-new. The reproduction-cost-new having once been ascertained may subsequently be kept up to date merely by adding the cost of extensions as these are made, and the "adequate" annual depreciation reserve, having once been ascertained, may be kept up to date, as extensions are made, by adding sums sufficient to reproduce the cost of each such extension at the termination of its useful life.

If past depreciation reserves, with interest accretions, have been no more than adequate to offset the accrued depreciation on the date of the valuation, either method will result in justice both to the consumer and to the owner. The choice of method is merely a question of convenience, and generally it will be found most convenient to predicate rates on reproduction-cost-new, at the same time limiting the annual depreciation reserve to the "adequate" annuity, as previously defined.

The exception to which the writer has referred is presented by the case, briefly touched on by Mr. Alvord, and also discussed by Henry Floy, M. Am. Soc. C. E.,* in which certain large properties, after suffering an initial depreciation, reach a stable stage in which they may afterward be maintained by the expenditure of certain sums each

* "Valuation of Public Utility Properties," p. 194.

Mr. Knox.

year for replacements, the cost of these replacements being charged to operating expenses the same as ordinary wear and tear. To quote Mr. Floy:

"The Receiver of the Third Avenue Railroad in New York City, operating a large property having numerous physical elements so that all deterioration became simply 'wear and tear' and a part of operating expenses, declined to obey the order of the Public Service Commission and provided no depreciation fund whatever, simply removing deterioration when it occurred and charging it as maintenance in operating expenses."

If past depreciation reserves, with interest accretions, have been no more than "adequate" to offset "accrued depreciation," all subsequent depreciation on a property which has reached this stage of stability, may properly be taken care of in either of two ways:

1st.—By continuing the "adequate" annual depreciation reserve; in which case rates must be predicated on reproduction-cost-new.

2d.—By providing annually, in the manner adopted by the Receiver of the Third Avenue Railroad, a sum sufficient in itself to take care of all subsequent depreciation, in which case rates should be predicated on depreciated reproduction cost.

By the second method the annual depreciation reserve is in excess of an "adequate" reserve, as previously defined, and it is for this reason, and for this reason alone, that rates may be equitably adjusted to yield a fair return on a value less than reproduction-cost-new.

Consider, for example, a plant composed of five elements of equal value and variable life expectancy as shown in Table 4.

TABLE 4.

Element. (1)	Reproduction-cost-new. (2)	Life expectancy, in years. (3)	Annual depreciation reserve to refund reproduction-cost-new at termination of useful life, sinking-fund basis. (4)
A	$1 000	25	$24.01
B	1 000	30	17.83
C	1 000	35	13.58
D	1 000	40	10.52
E	1 000	45	8.26
Total, or average...	$5 000	.....	$74.20

Assuming the scrap value to be nothing, the orthodox way of providing for the future depreciation on such a plant would be to set aside each year from the beginning of operation sums sufficient to amortize the reproduction-cost-new of each element at the end of its

Mr. Knox.

useful life. The annuities so required, estimated on a 4% sinking-fund basis, are given in Column 4 of Table 4. The total annuity required is $74.20. At the end of the twenty-fifth year, element *A* must be replaced, and the cost will be met by withdrawing from the depreciation fund the $1 000 accumulated by the annuity of $24.01 provided for this purpose; but, as the new element, *A*, will also have a life expectancy of twenty-five years, at the end of which it must again be replaced, the annuity of $24.01 provided to cover depreciation on element *A* must be continued and the total annuity will remain $74.20 as before. It will remain so indefinitely as long as no additions are made to the plant. Whether it be placed in bank or in trust at 4% interest, or invested in other ways, the annuity of $74.20 will, together with all the interest accretions with which it may fairly be credited, just take care of future depreciation, and no more.

Assuming that the owner actually makes such an annual reserve, the amount amortized at the end of the twentieth year will be $2 209.65, which amount may be taken to represent the accrued depreciation on that date. The depreciated reproduction cost at the end of the twentieth year will then be $5 000.00 — $2 209.65 = $2 790.35. As the owner can by hypothesis derive no "private gain" from the depreciation fund, however it may be invested, he must, so long as he provides for depreciation in this way, be allowed to earn a fair return on reproduction-cost-new.

Now assume that at the end of the twentieth year the owner perceives that 5 years hence he must replace element *A* at a cost of $1 000. He realizes further that at the end of each succeeding 5-year interval he must replace one element of his plant at a cost of $1 000. He estimates that the annuity necessary at 4% compound interest to produce $1 000 at the end of 5 years is $184.63, and he elects to take care of all subsequent depreciation by reserving this amount each year from earnings. The future cost to the consumer under this scheme will be increased in the annual sum of $184.63 — $74.20 = $110.43, and he must, obviously, if he is to avoid loss, obtain a reduction in the plant value or capitalization on which the owner is allowed to earn a fair return. Nor will the owner under these circumstances suffer any loss by such reduction in value. He has, in a sinking fund or otherwise invested, at the end of the twentieth year $2 209.65, equal to the accrued depreciation on his property as of that date. Under the first or orthodox method of providing for replacements, this sum, together with its earning power, was necessary to the proper provision for depreciation. Under the second scheme, neither the sum nor its earning power is so required. On the date on which the owner changes over from the first to the second method of providing for future depreciation, this fund is released or set free, and may henceforth be used productively by the owner in any way he sees fit. The consumer has in effect, by permit-

Mr. Knox.

ting the change in method, refunded to the owner, free and clear, a portion of his original capital equal in amount to the accrued depreciation on the property. Henceforth the owner's investment in plant is equal, not to the reproduction-cost-new, but to the depreciated reproduction cost, and this therefore is the sum on which he should be allowed to earn.

The case presented is only a special one under a general rule in which the interests of convenience are served by lowering below reproduction-cost-new the value on which the owner is allowed to earn a fair return, at the same time increasing above the "adequate" depreciation allowance, the sums annually set aside out of earnings to offset deterioration. It is in no sense an exception to the general law that where depreciation reserves are only "adequate" reserves, as previously defined, rates must be predicated on reproduction-cost-new.

The application of the general law will usually be more convenient, and will always result in justice both to the public and to the owners, unless we regard as an exception the case in which the owner has actually, during the past, set aside from earnings as an offset to deterioration an annual sum more than sufficient to take care of the depreciation which has occurred, or, what amounts to the same thing, unless the owner has actually during the past enjoyed excessive profits for which he is now to be penalized.

A reduction in the value on which he is now permitted to earn may be logically justified on this ground only in the event that the present owner has benefited from these extortions. Even on this supposition, the logical and scientific procedure is to take as our point of departure the basic principle that in the absence of such complicating considerations, the owner should be allowed to earn on reproduction-cost-new; then to apply proper and specific allowances for such irregularities as the history of the plant may disclose. In this way "the punishment" may be made "to fit the crime," and we will always know, at least by how much and why, we have lowered or increased below or above reproduction-cost-new the value on which the owner is entitled to earn a fair return, for it must not be forgotten that it is a poor rule which does not work both ways, and if an owner is to be penalized for "excessive" depreciation reserves or exorbitant profits made in past years, consistency demands that he be compensated for his past failure to provide "adequate" depreciation reserves and fair profits.

If, for example, the owner in the case just discussed, has during the first 20 years, in which the necessity for replacements was not conspicuous, made no reservations whatever for depreciation, but has been satisfied to earn a fair return on his investment in addition to operating expenses, in the expectation that future replacements may be provided for as a part of operating expenses, when the occasion arises it is evident that his capital will be impaired by an amount ($2 209.65) equal

to the accrued depreciation if rates are adjusted in the twentieth year to yield a fair return only on depreciated reproduction cost. In this instance, however, the loss is largely the result of his own folly, in failing to make provision at the proper time for the deterioration which was taking place. Mr. Knox.

He would be obliged to incur the same loss if he undertook to sell the property in the twentieth year, as it cannot be presumed that the physical elements of the plant could be sold on that date for an amount greater than their depreciated reproduction cost.

Mr. Humphreys, in discussing this question in the paper to which the writer has previously referred, quotes an amusing illustration taken from what he characterizes as the most logical paper on this subject he has ever read. The quotation is credited to a brief by Charles F. Mathewson, of the New York Bar, in the case of Kings County Lighting Company *vs.* The Public Service Commission for the First District of New York. Mr. Mathewson was the trial lawyer for the Company in the New York Consolidated Gas Company's case. The quotation follows:

"The proposition [to deduct 'accrued depreciation' in valuing plants in rate-making] is so absurd on its face that it hardly needs discussion to show its fallacy. Why, aside from the question of 'confiscation,' should consumers, for exactly the same service, equally efficiently rendered, expect to pay less in the sixth year than in the first year, merely because some items of plant will (viewed at the sixth year) require replacement at a date in the future then nearer than such date was at the beginning of operation? As well might it be claimed, to repeat a homely illustration, that a farmer should regulate the price of the eggs which he sells, by the age of the hen which lays them—reducing the price of the product as the hen gets on in years. The reason he does not is that the service efficiency and operating value of the hen, as evidenced by the quality of the eggs which she lays, are not impaired by the fact that her life is advancing. That advancement may concern the farmer and possibly concerns the hen; but it in no manner affects the value of the eggs to the consumer, or justifies him in demanding them at a lower price than he paid at an earlier period of her life. The consumer of the eggs must expect to pay a sufficient price to afford a return to the farmer on his total investment in the hen during her life, *plus* enough more to enable the farmer on her death to replace her, and thus keep his investment unimpaired. A farmer could hardly be expected to invest in hens for the purpose of supplying the public with eggs, if for a portion of their life he was to receive a return on only a third or a half of his investment; and any such rule would simply compel the public to go without eggs until the regulating power (if such there were) saw fit to revise its reasoning. There is absolutely no difference in the economic principles applicable to the operation of a gas plant and the operation of a hennery, so far as concerns right to return on capital; and what is absurd in one case is equally absurd in the other. The fact that the rate of return in the one case is subject

Mr. Knox. to reasonable regulation, and not in the other case, has no bearing on the main proposition."

A consideration of this illustration in the light of the principles thus far set forth indicates that it is not of universal application except as an illustration of the fundamental principle which always holds where complicating considerations are absent. It presumes that the farmer charges no more than enough to afford a return on his total investment plus enough to keep his investment unimpaired. If, as some consumers think, the farmer charges enough in addition to a fair return on capital invested, to replace the hen several times over, prior to her demise, the absurdity of expecting a reduction in the price of eggs, even in this case, from a purely theoretical point of view, is not quite so apparent.

It is readily admitted that the preceding discussion has been carried on largely from a theoretical point of view; but, considering the present confusion of ideas on the subject, this theoretical treatment of the question appears to be fully justified. Sound practice, in this as in other engineering matters, must rest on a firm foundation of sound theory, and the establishment of this theory has something more than academic interest.

In concluding it may be well to point out that too much importance may easily be attached to the fact that the Supreme Court of the United States has in certain instances held that rates should be adjusted to yield a fair return only on depreciated reproduction cost. It is of course true that the last word in these matters rests with the Courts, and that Courts are much given to following precedent; but it must not be forgotten that Court decisions are usually rendered with a view to dispensing justice in the particular case before the Court. It has been shown that there may be circumstances in which the ends of justice are served by allowing an owner to earn a fair return on depreciated reproduction cost. Whether or not the cases so decided by the United States Supreme Court fall in this category we do not presume to say, but even this is unimportant because it cannot be presumed that the Courts will seek to perpetuate what can be demonstrated to be a wrong merely to avoid going against their own precedents. The question cannot be regarded as finally settled until it is settled equitably, and when, as in the present case, such a wide diversity of opinion prevails among those who have spoken most authoritatively on the subject, the attempt to reason the problem out *a priori* seems to be fully justified.

Mr. Gandolfo. J. H. GANDOLFO, ASSOC. M. AM. SOC. C. E. (by letter).—In a discussion dealing with appraisal, valuation, depreciation, rate-making, or kindred subjects, the argument is frequently advanced that no consideration must be given in cases in which all matters pertaining thereto have not been conducted in a fair, honest, proper, and business-

Mr. Gandolfo.

like manner. If the human race was still living in the Garden of Eden; if Pandora had never allowed all those troubles to escape into the world; if there were no such things as selfishness, greed, hate, envy, revenge, and a host of other evil passions; in short, if the great struggle for existence throughout the world (and this struggle applies to all plant and animal life, as well as to all members of the human race) did not exist, then it would be possible to discuss such questions purely academically, and arrive at such a course of conduct for all parties concerned as would lead the human race along a broad and happy highway of peace, prosperity, and contentment. Under these circumstances, the very necessity for such things as public service commissions, appraisals, hearings, judicial reviews, and hosts of kindred matters would not exist.

Unfortunately, however, the millennium is still as far away as ever. It is just such elements as those described in the first part of the foregoing paragraph that go to make up the human mind, and therefore such elements must be taken into consideration and given careful attention in such discussion. In other words, it is the much used term "human nature" that must be studied and reckoned with, and taken into account, in such investigations. Facts on record relating to bond and stock issues, and to general methods of financing and of business, especially in the railroad world, have made history, showing most conclusively that human cupidity and the still baser human passions have played a most important rôle in these matters from the year 1838 to the present day, resulting in the loss of millions of dollars to honest investors, both large and small.

Mr. Alvord says, on page 2048:* "In other words, no amount of accounting or theorizing can make good a depreciation fund which is actually not in hand". In the succeeding pages, however, he seems to lean to the idea that a sinking fund provided to take care of depreciation or obsolescence can be invested in some other enterprise and still remain a sinking fund, and goes into a great deal of detail to explain why this is so. For example, on page 2056,* he says: "* * * for instance, such moneys may be invested as new capital in new construction and extensions in the very plant itself to great advantage * * *."

Webster defines "sinking fund" as follows: "(*Finance*), a fund created for sinking or paying a public debt, or purchasing the stock for the government". The Century Dictionary and Cyclopædia gives the following: "A fund formed by a government or corporation for the gradual 'sinking', wiping out, or reduction of its debt, by various devices for the accumulation of money." Funk and Wagnalls' Standard Dictionary says: "A fund instituted and in-

Proceedings, Am. Soc. C. E., for November, 1913.

Mr. Gandolfo.

vested in such wise that its gradual accumulations will enable it to meet and wipe out a debt at maturity".

In view, therefore, of the very fundamental idea and *raison d'être* of a sinking fund to cover depreciation and obsolescence, it is an absolute impossibility to consider it as being invested in any other enterprise, except as a bank or trust company would invest such funds. The moment such a sinking fund is used by the owner of a plant or a board of direction for any purpose other than that for which it was originally set aside, the fund, as a sinking fund, ceases absolutely to exist. No longer can it be counted on as needed to replace the plant. It is gone, absolutely and entirely, as far as its original purpose was intended, and no amount of bookkeeping or argument can make anything else out of this fact.

On page 2054* Mr. Alvord says: "* * * there would be no difficulty or hazard in relying on the ability of the owner or owners to replace the sinking fund from outside sources * * *." On page 2055* he also says, "It may be objected that it is a hardship on owners of public utilities, who are able and willing to replace in the property such portion of the renewal fund at any moment * * *", and on page 2056,* "* * * the owner must be willing and ready to finance the replacements and depreciation fund, whenever the occasion therefor arises * * *." Admitting for the moment the willingness, suppose, when the time comes, that the owner is not able to do so? What then? And further, suppose that such a fund has been invested in some other way, or has been appropriated for some other purpose, and then the parties at fault, although fully able to do so, are not willing to make restitution when the fund is needed for its original purpose. Who is to make them do so?

In connection with this matter of the investment of a sinking fund, it may be argued that the bank or trust company in which such a fund would be deposited, to draw interest at ordinary rates, would invest these moneys in some way, and therefore there is practically no difference in the end, than if the owners invested the fund direct. There is a very great difference, however, which may be summed up as follows:

(1) The owner is an interested party, and as such, is not capable of investing the fund to as good advantage as the bank. He would be more apt to have bias or prejudice, good or bad, and it would be absolutely impossible for him to look at things in the free, untrammeled way that the officers and board of direction of a bank are supposed to do.

(2) The fund in question is not the only resource possessed by the bank. There are dozens of others, including capital and surplus, and

* *Proceedings*, Am. Soc. C. E., for November, 1918.

if one fails or is in such form that it cannot be realized on at once, there are others that can be. In this way, the bank may be likened to an equalizing pond or reservoir for the benefit of all its depositors. The drain in one direction may be heavy, while that in others is light, and at the same time there is a constant supply from all sources. This condition could not possibly exist if the fund was directly invested by the owner. Mr. Gandolfo.

(3) The bank or trust company is in its turn a "Public Service Utility", subject to the most careful scrutiny by the State, and thus an additional safeguard is thrown about all sums placed here in trust. If the fund was privately invested by the owner, there would be no such safeguards.

Further, if the owner, as stated by the author, must always be ready to make good the depreciation and obsolescence, he in his turn must have funds immediately available with which to do so. As, following out this line of argument, he would ordinarily have all his personal funds invested, it would then be necessary for him to maintain some fund for this particular purpose. Wherein lies the difference, then, under such conditions, whether such a fund is held by the original party, or must go through several hands, except the far greater risk and uncertainty in regard to its ever materializing at its original source when needed.

As far as investing a sinking fund in extensions to the plant, the moment it is so invested, it becomes "Capital", subject at once in its turn to depreciation, and is no longer "Sinking Fund". Further, if the same rate of profit is allowed on the sinking fund as on the plant (and, under conditions as hereinafter described, there seems to be no question but that there should be), then there is no difference as to whether the fund is invested in new construction or not, as far as the returns to the owner are concerned.

As for a concrete example illustrating much of the foregoing, there is one in the New York, New Haven and Hartford Railroad. The funds of this road, which should have been used to take care of depreciation, obsolescence, and improvement, within the last few years have been used for other purposes, the details of which it is needless to go into here. When, a short time ago, on account of a series of accidents that cost the lives of scores of people, an investigation by the State disclosed the fact, among others, that sections of this road were still equipped with signals of a type which had been discarded as obsolete by other roads some fifteen or more years ago, and it therefore became imperative to use for improvements the funds that had been otherwise "invested", did the parties who had appropriated them make any move to replace them? When public opinion, however, at last aroused, demanded that something be done, $67 552 000 of 6% convertible debenture bonds were offered to the general public, in order to take care of some $46 023 750 of obligations which are to mature within com-

Mr. Gandolfo.

paratively short periods, the remainder being to pay for financing and to obtain funds to make good the depreciation and obsolescence. The issue of these bonds has been opposed by the present bondholders, and the offering of them is now awaiting the decision of the Court. In place of this, approximately $45 000 000 of short-term notes were issued, to pay for the immediately maturing obligations, and also to provide for pressing needs due to depreciation and obsolescence.

Further examples, such as the foregoing, might be given in detail, but there is very little use or profit to be gained by anybody in arguing theoretically about a question of this kind, when undeniable facts and occurrences are on record before the financial world and the general public.

As the author points out, at no time should a depreciation and obsolescence fund amount to a very large percentage of the cost of the plant, on account of the constant withdrawals from it to maintain the plant in first-class and up-to-date condition. If such a fund is actually in hand, that is, actually in trust, there is no question but that rates should be allowed on it, just the same as on any other item of the plant. If the plant is being kept in repair and up to date by constant withdrawals from the fund, there seems to be no reason that rates should not be allowed on the full invested capital of the plant. This matter can be treated in two ways, which lead to the same result: The property can be appraised at its full cost, without depreciation, and returns can be allowed on this figure, no special mention being made of the fund; or the property may be appraised at its cost, less depreciation, and returns may be allowed on this, and also on the depreciation fund. Of course, it is assumed that the sinking fund is always approximately equal to the actual depreciation at any time. A sinking fund, provided for depreciation and obsolescence, and actually in hand, is part of the plant, and should be treated as such.

The necessity of keeping a public utility property in first-class condition by constant withdrawals from the sinking fund can be further illustrated by the following theoretical case. Suppose that the life of the physical property has been determined, and then a depreciation fund is created which, at the end of the period, will just return 100% on the investment. At the end of this period, the plant, like the deacon's famous "one-hoss shay", would theoretically vanish into thin air, leaving the sinking fund in its place. If a fund under such conditions was allowed to accumulate, then the theory that a public service utility must render adequate and constant service to the public is untenable, and cannot be upheld, as the owners would have a perfect right to allow the plant to deteriorate gradually to nothing, or to wipe out the utility at such time as they saw fit, and leave the public without its benefits.

Mr. Gandolfo.

This question of constantly keeping up the depreciation of a property is referred to in Knoxville *v.* Knoxville Water Co., 212 U. S., 1, Jan. 4, 1909, which says that the Company "* * * is entitled to see that from earnings the value of the property invested is kept unimpaired, so that at the end of any given term of years, the original investment remains as it was at the beginning". That public service corporations are expected to keep the plant up to date, without allowing any excessive accumulation of a sinking fund, is shown by the opinion of Judge Evans in Cumberland Telephone and Telegraph Co. *v.* City of Louisville, 187 Fed., 637, April 25, 1911, and that of Judge Haight in People *ex rel.* Manhattan Railway Company *v.* Woodbury, 203 N. Y., 231, Oct. 17, 1911.

On page 2055,* Mr. Alvord argues that if a sinking fund has been withdrawn from the plant and used for other purposes—or, as he puts it, for private gain—then the owners are not entitled to rates on it. The writer fails to see why it is necessary to argue on such a point as this, as it is a self-evident fact. If rates were to be allowed on something in the way of a sinking fund that does not exist, then it would be just as logical to remove an entire battery of boilers (or any other part of a plant), erect and use them in some other place, and then claim rates on their value, on the ground that the owners would replace them if needed. Thus the argument might be continued *ad infinitum* until the best part of a plant had been removed and rates were still being allowed on it as originally installed.

On page 2060,* under the 5th conclusion, the author says: "That though it is not now considered improper to use reserve or sinking funds allowed for depreciation for private gain * * *". The writer hardly thinks that Mr. Alvord can have realized what he was saying when he made this statement, or else that he did not mean what he says. If a private individual owns a plant himself, and sets aside a sinking fund for depreciation, and then after a time withdraws this fund and uses it for some other purpose of his own, but still calculates that he has a depreciation fund, he simply deceives himself—and there is no deception so fatal as self-deception. If, on the other hand, the concern is a stock company, and a sinking fund for depreciation and obsolescence has been created, and then the officers, directors, or managers should use this fund for their own private gain, it would amount to misrepresentation and fraud to both stock and bond holders on the one hand, and misappropriation and embezzlement of funds on the other, both of which are criminal offenses under our penal code. Furthermore, even if a board of direction did use such a fund in some other way, even if for the direct benefit of the stockholders, it is very doubtful if, under a strict code of ethics, it would have a moral right

* *Proceedings*, Am. Soc. C. E., for November, 1913.

Mr. Gandolfo.

to do so, without first having obtained the majority vote of the stockholders to such a venture; although, in such a case, the strict letter of the law would doubtless uphold a board in such a proceeding.

In conclusion, it may be said, therefore, that a sinking fund to cover depreciation and obsolescence must be kept constantly in hand, and be available at all times; that constant withdrawals must be made from this fund to keep the plant in first-class and up-to-date condition (that is, 100% efficiency and value); that such a fund cannot be invested in other enterprises, as then it is no longer available for its purpose, and does not exist; and that, unless such a fund, or its equivalent in some form or other, exists, the plant is not entitled to full cost or replacement value, but must be appraised on a basis of cost or replacement value less depreciation.

STRESSES IN WEDGE-SHAPED REINFORCED CONCRETE BEAMS.

Discussion.*

By Messrs. A. C. Janni and L. J. Mensch.

Mr. Janni.

A. C. Janni, M. Am. Soc. C. E. (by letter).—Before entering into any discussion on the opportunity and legitimacy of the assumption on which this work hinges, the writer wishes to call the author's attention to a little mathematical "license" which he took in simplifying the expression, $P\,Q = \frac{v \sin.\alpha}{\cos.(\alpha + \beta)}$,† because it undermines, perhaps, the whole mathematical "make-up" of all the formulas which depend on that *"lapsus calami"*.

There is no doubt that, as α tends toward zero, $\sin.\alpha$ may be substituted for α; this simplification being entirely legitimate; but, if α tends toward zero, the expression $\cos.(\alpha + \beta)$ does not tend toward $\cos.\beta$, by any means.

The author knows that $\cos.(\alpha + \beta)$ is purely a symbol of a certain operation to be performed, and is not an actual value; its value is given by $\cos.\alpha \cos.\beta - \sin.\alpha \sin.\beta$, and it is on this latter that he may operate his simplification. Thus his $P\,Q = v\,\alpha \sec.\beta$ should become $P\,Q = \frac{v\,\alpha}{\cos.\beta - \alpha \sin.\beta}$, when it is assumed that α tends toward zero, to be a mathematically correct simplification.

Concerning the assumption adopted by the author in order to find a "workable formula" for the compressive stress in concrete, and

* This discussion (of the paper by William Cain, M. Am. Soc. C. E., published in the November, 1913, *Proceedings*, but not presented at any meeting of the Society) is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† See foot-note, *Proceedings*, Am. Soc. of C. E., for November, 1913, p. 2070.

Mr. Janni.

also some of his statements, the writer cannot quite agree. Two questions are before him, namely:

1. Do we need that formula?
2. Is that formula worked out correctly?

It is the writer's opinion that neither of these questions can be answered in the affirmative.

Theory is quite competent to take care of a design of a wedge-shaped beam, if necessary, despite what the author says. If the cross-section of a wedge-shaped concrete beam is rectangular and the angle, β, is not large, the common formula for bending is sufficiently good to give the maximum compressive stress in the concrete.

It is a fact that the formula entails the truth—which, by the way, is not a postulate—demonstrated by Saint-Venant, that all bending stresses at any point act perpendicularly to the cross-section; but this, in the case where β is not very large, does not prevent the formula from giving a result sufficiently near to the truth to insure the maximum stress.

That the direction of the maximum stress, in the case of Fig. 1, is parallel to the top, $N\ M$, of the beam, and on which the author lays so much stress, is, nowadays, mathematically ascertained.* In the case of a dam design, that direction is of capital importance, and the failure to recognize it, or the overlooking of it, in the design of some dams, has often been the cause of loss of thousands of innocent lives and, perhaps, millions of dollars. In a wedge-shaped beam, however (or in a counterfort), the conditions are such that the direction of the maximum compressive stress can be ignored in most cases.

If the cross-section of the wedge-shaped beam is not rectangular, then, with proper limitations, the usual formula to determine the principal stresses, reported in many textbooks, can be used. This formula is, precisely, designed for a beam by taking as unknown quantities certain inclined stresses, called "principal stresses", instead of the normal stresses in that section, and, really, this is the most logical way of designing a beam, although the common practice, for opportune reasons, follows that of the bending and shear formulas.

Winkler, in 1867, as far as the writer knows, wrote on this subject, and, after him, Culmann, Ritter, Guidi, and others treated the same question; so that the conception cannot appear novel, as the author seems to think, at least judging by some of his remarks.

If, finally, the inclination of $N\ M$, Fig. 1, is large, then Grashof's formula, with due limitations for the case of reinforced concrete, may be used.

In view of all the foregoing considerations, the writer thinks that there is no need of a formula for the case in point, and that, after all

* M. Levy, *Annales des Ponts et Chaussées*, 1897; and F. Platzmann, *Ueber den Querschnitt der Staumauern*, Leipzig, 1908.

the arbitrary assumptions of the author in reaching his "workable formula", admitting its correct mathematical "make-up", its results are much farther from the truth than those given by the existing formulas, which, in all cases, are very reliable. Mr. Janni.

It is necessary, accordingly, to take into consideration the author's assumption in finding that formula, and, as a consequence, its mathematical reliability.

As the writer said before, it is very well known that the extreme top compressive stress is parallel to the beam top as, disregarding the friction on the soil, Fig. 1, the maximum tensile stress is parallel to the bottom, *L I*.

The author states that the maximum tensile stress at that region of the beam would be parallel to *L I*, if the beam were a homogeneous one.

Even if the beam were homogeneous, if friction is not disregarded, the maximum tensile stress, at the bottom of the beam, is not parallel to the bottom face.

When the beam is heterogeneous, as in the author's case, equilibrium conditions do not change, if friction is included; the only difference being that, as usual, the tension in concrete is disregarded, so that the designer is inclined to disregard its direction, also, unless it is not a case of scientific research.

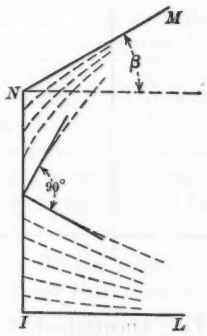

FIG. 9.

Now, the maximum compressive stress being parallel to the top, and the maximum tensile stress (always disregarding friction) being parallel to the bottom, the intermediate bending stresses, the author says, change their direction gradually from *N M* to *L I*, Fig. 1. As a matter of fact, those intermediate bending stresses do not change their direction gradually in the way the author means. Fig. 9 gives an idea of the behavior of the internal stresses in the cross-section, *N I*, on account of the angle, β. The author, however, states that, for the purpose of finding "workable formulas", he must assume that the intermediate compressive bending stresses be parallel to the maximum compressive bending stress. Such an assumption cannot be justified, when it is well known how those stresses act, and a designer knows how to determine them. Their direction, which is not constant for all, is a function of the angle, β, and not of cos.β, and their position is farther and farther from the author's assumption as β increases.

Apart from this assumption made by the author, which does not seem justifiable to the writer from any point of view, it is interesting to study the formula itself.

Mr. Janni.

Formula 8, which, according to the author, gives the maximum compressive stress in the concrete, will be taken into consideration. For the sake of clearness, the writer will compare the theoretical formula for bending in a beam of constant cross-section, which, when β is not very large, may be used without any fear of going astray, with the author's formula for the same kind of stresses in a wedge-shaped beam, using for both the same lettering, Fig. 10.

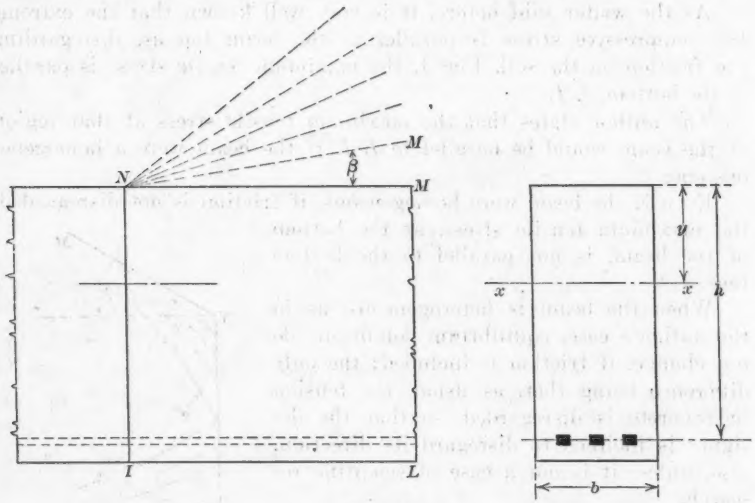

FIG. 10.

The theoretical formula for bending in a beam of constant rectangular cross-section is

$$f_c = \frac{2\,M}{b\,y\left(h - \frac{1}{3}y\right)} = Q \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

The author's formula for bending in a wedge-shaped beam is

$$f_c = \frac{2\,M}{b\,y\left(h - \frac{1}{3}y\right)\cos.^2\beta} = \frac{Q}{\cos.^2\beta} \quad \ldots\ldots\ldots\ldots (23)$$

It is plain, as the author says, that Formula 23, for $\beta = 0°$, becomes Formula 22.

Formula 23, however, as given by the writer, presents some other information rather interestingly.

Suppose that $N\,I$, Fig. 10, be a constant section, and that the line, $N\,M$, rotates about N, the angle, β, increasing gradually while M (external moment), keeps constant, the section, $N\,I$, according to

Formula 23, becomes weaker and weaker, until, when $\beta = 90°$, it has no resisting power whatever. Mr. Janni.

The writer does not think any comment necessary, except to recall the closing words of the paper: "The writer believes that he has effected a practical solution which is on the side of safety and may commend itself to the practitioner."

It is to be added, however, that Equation 8 is not the only equation by the author which leads to such conclusions; Equation 7, for instance, and its derivative equation for "rough computations," as the author designates it, are of a similar statical consistency.

Equation 3 has been worked out to enable the finding, according to the author, of the position of the neutral axis.

It is not clear to the writer, however, why the author gives a rather long equation (which, by the way, is not correct), when there are already several plain methods of finding that axis in a reinforced concrete beam.

The writer thinks it would be necessary for the author to devote a few words in justification of his point of view concerning Equation 3.

The writer, in closing, would like to ask the author the reason for his statement that "The unit stress, v, acts parallel to $N\ N'$". The writer has the impression that this statement, as put by the author, is not another of his assumptions, but a true and proper theorem concerning the equilibrium of internal forces in a wedge-shaped beam; and, as such, he would like further explanation.

L. J. Mensch, M. Am. Soc. C. E. (by letter).—In the discussion of a paper on reinforced concrete construction before this Society several years ago, the statement was made that the counterforts of retaining walls do not act as beams. This alone would show that Professor Cain's paper is important. It also seems that the writers of textbooks have neglected to devolop theories of wedge-shaped beams, although quite a number of such books contain theories nearly identical with that of Professor Cain, for curved beams such as crane hooks, arched girders, etc. Mr. Mensch.

Professor Cain points out that an engineer is apt to overlook the fact that the compressive forces must be multiplied by $\cos.^2\beta$ when entered in the elastic equation, instead of by $\cos.\beta$ which one would be likely to do without going deeper into the matter. Probably a great many mistakes are made on this line, yet it is strange that they are made for the compression side of the beam, though on the tension side it is quite natural to multiply the actual cross-section (which is the $\cos.\beta$ value of the section made by the plane, $I\ N$) by $j\ d\ \cos.\beta$ to find the moment of the tensile forces.

For compression members, in trusses with inclined members, engineers are also accustomed to consider only the cross-section at right

Mr. Mensch.

angles to the direction of the stress; therefore, it appears to the writer that only carelessness or incompetence is the cause of the mistake complained of. Professor Cain's theory stands and falls with the fact that plane sections remain plane after deformation.

His assumption that the compressive forces are parallel to the compression face is certainly permissible in all cases where the percentage of reinforcement is low, say, less than 1%, and errs only slightly on the side of danger.

The law or assumption of plane sections remaining plane after deformation is certainly one of the greatest inventions of modern engineering, and enabled us to obtain a great number of simple working formulas, where formerly rules of thumb were used, yet the law is not universal, and is strictly proven only for straight beams of high-grade iron of rectangular section, within the elastic limit, and never for the neighborhood of ultimate load.

Professor Schule, of Zürich, about 12 years ago, proved that this assumption does not hold good for reinforced concrete beams, even under light loads, and why engineers all over the world have utterly disregarded these important tests is certainly strange.

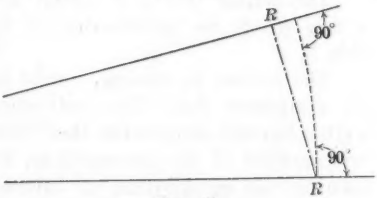

FIG. 11.

It is a well-known fact that the plane-section theory for plain concrete beams gives results which vary just 100% from actual tests, and still the same theory is applied to reinforced concrete beams. R. L. Humphrey, M. Am. Soc. C. E., in the discussion of his painstaking tests of 343 reinforced concrete beams, declares that the compressive stresses in the concrete and the tensile stresses in the reinforcement often differed 50% from the theory. In the face of such facts it may be expected that Professor Cain's table will differ just as much from facts, although it is much better than relying on a mere guess.

Tests of cast-iron beams prove that such wedge-shaped beams fail on a curved surface which is tangent to perpendicular lines to both faces of the beams, as shown in Fig. 11. For this reason the writer has advised* calculating such a counterfort for a section, $R\,R$, like a common beam, which greatly simplifies the computations and errs on the safe side. Engineers are accustomed to making a similar assumption in case of concrete arches, when they determine the stresses in a section at right angle to the center line of the arch. In view of this fact, it would be well to calculate the fillet in Fig. 4 along a line about bisecting the angle, $N'\,N\,I$, which will be found the dangerous section.

PAINTING STRUCTURAL STEEL: THE PRESENT SITUATION.

Discussion.*

By Messrs. Allerton S. Cushman and Samuel Tobias Wagner.

Allerton S. Cushman, Assoc. Am. Soc. C. E. (by letter).—Mr. Sabin's exposition of the present situation in regard to paint protection of steel would appear to have at least the merit of simplicity. In a few brief paragraphs he sums up all that he cares to consider of the researches, theories, and conclusions of contemporary investigators of corrosion and paint problems, and sets forth what he terms the "whole history" of this "jargon" about inhibition and stimulation, which he states never had any particular value to the consumer, and is generally used to mislead him. Mr. Cushman.

It does not seem fair or just that such a statement should be allowed to pass unchallenged, in view of the great number of engineers and others who are responsible for the care of steel structures and believe in the value of the "inhibitive" quality of protective coatings.

Mr. Sabin's review entirely ignores the electrolytic theory of the mechanism of the reactions which lead to metallic corrosion, and brushes aside all its application to paint problems, as of little or no value. Ignorance, even in the purest sense of the word, of a mass of accumulated evidence and data, is not argument, and is likely to be considered on a par with King Canute's effort to order back the advancing tide. The electrolytic explanation of corrosion, on which the inhibitive theory of paint protection is based, is now accepted by a great number of investigators and authorities in America and abroad. As the writer, to the best of his knowledge and belief, is largely re-

*This discussion (of the paper by A. H. Sabin, Assoc. M. Am. Soc. C. E., published in the November, 1913, *Proceedings*, and presented at the meeting of Jauuary 7th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Cushman.

sponsible for the "jargon" which Mr. Sabin claims has done so much to deceive consumers, he may perhaps be permitted to contribute a few paragraphs to Mr. Sabin's "whole history" of the subject under discussion. As far as the writer is aware, the first use of the words "inhibition" and "stimulation", as applied to corrosion and protection problems, occurred in his paper on "The Corrosion of Iron".* In that paper the electrolytic theory of corrosion was developed. A few excerpts from this paper will serve to illustrate the point made:

"It has long been known that rusting is inhibited and that polished iron will remain bright indefinitely in all sorts of alkaline solutions, provided they are sufficiently concentrated. This is also true of all solutions of salts of strong bases and weak acids which hydrolyze to an alkaline reaction. This fact has been eagerly seized upon by the adherents of the various theories which have been advanced, as it can be made to fit in more or less well with them all. Thus, alkalies absorb carbon dioxide, and therefore carbonic acid is prevented from carrying on its work of destruction. The added fact that fully saturated bicarbonate of soda also provides full protection to iron, even in fairly dilute solution, which would seem to be a stumbling block, has not shaken the faith of the devout believers in the carbonic acid theory.

* * * * * * * *

"Solutions of chromic acid and its soluble salts, such as the chromate and bichromate of potash, inhibit the rusting of iron immersed in them.

* * * * * * * *

"The writer has observed that if a rod or strip of bright iron or steel is immersed for a few hours in a strong (5 to 10 per cent.) solution of potassium bichromate, and is then removed and thoroughly washed, that a certain change has been produced on the surface of the metal. The surface may be thoroughly washed and wiped with a clean cloth without disturbing this new surface condition. No visible change has been effected, for the polished surfaces examined under the microscope appear to be untouched. If, however, the polished strips are immersed in water it will be found that rusting is inhibited. An ordinary untreated polished specimen of steel will show rusting in a few minutes, when immersed in the ordinary distilled water of the laboratory. Chromated specimens will stand immersion for varying lengths of time before rust appears. In some cases it is a matter of hours, in others of days or even weeks before the inhibiting effect is overcome.

* * * * * * * *

"If iron or steel is brought into contact with water, either pure or natural, iron goes into solution by replacing the hydrogen ions that are present, and if oxygen is present, the ferrous ions are oxidized with the formation of ferric hydroxide in the form of rust. Any substance which increases the concentration of the hydrogen ions in the water, such as carbonic, sulphuric, or other acids, will stimulate corrosion. On the other hand, any substance which decreases the concentration of the hydrogen ions, or in any manner prevents the interchange of

* *Proceedings*, Tenth Annual Meeting, Am. Soc. for Testing Materials, June, 1907, p. 211.

the electrostatic charge between the metal and the hydrogen ion, will inhibit corrosion. It follows from this that the rusting of iron is primarily a hydroxylization rather than an oxidation, and the oxygen does not directly attack the surface of the metal in the wet way or at ordinary temperatures. Mr. Cushman.

* * * * * * * *

"Substances which increase the concentration of hydrogen ions, such as acids and acid salts, stimulate corrosion, while substances which increase the concentration of hydroxyl ions inhibit it. Chromic acid and its salts inhibit corrosion by producing a polarizing or dampening effect which prevents the solution of iron and the separation of hydrogen."

These citations are sufficient to show the writer's responsibility in the application of the words "inhibition" and "stimulation" to the discussion of corrosion problems. In the same paper, the practical application of the use of chromic acid and its salts as an inhibiting agent was suggested and foreshadowed in the following words:

"From what has been shown in regard to the inhibitive action of the chromates it is not improbable, since such dilute solutions prevent electrolysis and corrosion, that the addition of small quantities of bichromate to boiler waters would be highly efficacious in preventing the rapid pitting which has caused so much trouble.

* * * * * * * *

"The experiment has been made of keeping iron and steel in dilute boiling solutions of bichromate, through which a current of air is bubbled, for protracted periods, and as long as the strength of the solution was equal to or above one or two pounds of bichromate to 1 000 gallons of water no rusting has ever taken place. There would, therefore, seem to be no reason why potassium bichromate should not come into use as a boiler protective. The application of the various inhibitors in the priming coats of paints and other protective coverings has already been to some extent made use of, and it would appear that slightly soluble chromates should be theoretically the best protectives for the first application to iron and steel surfaces."

At the 1908 meeting of the American Society for Testing Materials the writer presented a paper entitled "The Inhibitive Power of Certain Pigments on the Corrosion of Iron and Steel", and in that paper the whole subject of the inhibitive theory as applied to paint protection was developed further.

Following the presentation of the writer's 1907 paper, and in the discussion of a paper by Mr. L. S. Hughes, entitled "The Deleterious Ingredients in Paints", Mr. G. W. Thompson, who is quoted by Mr. Sabin, suggested the water pigment tests as described by Mr. Sabin, and described some experiments which he had already made on this subject. Mr. Thompson, in the course of his remarks, stated that the remarkable thing which appeared in his original experiments was that some of the pigments had inhibited the oxidation, one pigment having

Mr. Cushman.

caused a loss to the steel test piece of 0.37%, showing, according to Mr. Thompson's own words, a large inhibition, whereas another pigment had caused a loss of 2%, a considerable increase, as compared with the blanks which were run simultaneously. Mr. Thompson summed up by stating that he wished to make the suggestion to Mr. Cushman, Mr. Walker, and others who were investigating the corrosion of iron, that they make experiments to discover the relative electrolytic activity of various pigments in relation to iron. This suggestion was eagerly accepted by the writer, and, as Mr. Sabin describes, a committee of five chemists, from different parts of the United States, made a series of tests of the principal pigments on steel immersed in water. The results obtained by these laboratory investigations were then placed on the practical scale of experimentation by the steel test fence erected at Atlantic City by the Paint Manufacturers' Association of the United States, the inspection of which from time to time was placed under the supervision of suitable committees of the American Society for Testing Materials. As a result of these tests, which have been carried on constantly since 1908 and have been reported on annually, the best protection has been developed by the basic chromate of lead known as American vermilion. The pigments which received the five leading grade-marks in these tests depend on the chromate principle of inhibition. A number of the other leading pigments depend on the basic principle of inhibition, including both the orange mineral and red leads, which have also ranked comparatively high in the tests.

In spite of this, Mr. Sabin states:

"It is obvious that in a good paint the pigment particles are enveloped in a film of oil; they do not come in contact with the iron; if they did, the paint would peel off, for no dry pigment adheres well to metal. It is as true to-day as it has been in the past that steel rusts because air and moisture act on it; and paints are used to keep air and moisture from it. They do not inhibit rusting, except as they inhibit the cause of it."

This statement would appear to show that Mr. Sabin has not comprehended the manner in which inhibitive pigments tend to protect steel when mixed with oil and painted on the surface of the metal. No intimate contact of the pigment particle and the underlying surface is in fact necessarily called for, in order that the inhibitive action should be exerted. A simple experiment can be made to prove this, by any one interested in making it. If a slightly soluble chromate, such as zinc yellow or the precipitated chromate of calcium, is mixed and ground with linseed oil, painted on a steel surface, and allowed to harden in the air in the ordinary way, and if this painted steel specimen is then immersed in water, it will be found by the gradual yellowing of the water that a small part of the chromate pigment is capable of dissolving in the water and even of being leached out of

the film. This simple experiment shows that when a chrome inhibitive paint is used for protecting iron and steel, the water of the atmosphere which condenses or rains on a surface and is absorbed by the linoxyn coating, impregnates itself to a slight degree with the chrome radical of the pigment. This solution wets the metallic surface and to some extent maintains it in a passive or non-rusting condition. Though it is true that an ideal paint film should succeed in keeping air and moisture from the underlying surface, the fact is that paint films do not exhibit ideal qualities in this respect, and all of them are more or less permeable to water and atmospheric gases. Mr. Cushman.

It is well known that for many years red lead has been used more or less successfully as a prime coating material on iron and steel, and the writer has no criticism to make of properly manufactured red leads which are properly mixed with a good vehicle and properly applied to steel. Unquestionably, it must be admitted that these red lead prime coaters yield good protection. When, however, Mr. Sabin claims that nothing more can be done, and that there is no need of further investigation of paint protection problems, the writer must take issue with him, as it can easily be shown under test that, based on the inhibitive explanation of protection, many pigments are capable of giving better protection than even the best red lead. As a matter of fact, if the use of red lead as a prime coating material has already solved the problem of protecting steel to the maximum degree, it may well be questioned why it is that so large a percentage of structural steel all over the world is suffering from rapid corrosion and deterioration. Most of the inhibitive prime coating materials must inevitably cost more than red lead, and where, as is generally the case, the first cost of application is a factor of the highest importance, red lead will probably continue to be generally used. It is the writer's belief, however, that where the first cost of application is considered in relation to the maintenance or upkeep cost of structural steel for a number of years, it is now possible, as the result of research and investigation, to design an inhibitive prime coating material which will protect steel more efficiently than the usual red lead application, and he sincerely hopes that engineers and other consumers will not remain satisfied that the last word has been said with respect to paint protection in Mr. Sabin's presentation of the present situation in regard to the painting of structural steel.

Samuel Tobias Wagner, M. Am. Soc. C. E. (by letter).—The question of the selection of a proper paint to be used on a steel structure is one of the greatest importance, and much progress has been made in the last generation toward obtaining purer materials and applying them in a more workmanlike manner. For a number of years the writer has been of the opinion that it was not fair to expect any single Mr. Wagner.

Mr. Wagner.

paint to give the best results under different conditions of climate and exposure, and that generally specific conditions could be ascertained to determine which kind should be used. Throughout this discussion there were two general features which were kept prominently in the foreground; First: the materials should have a high degree of purity; Second, they should be very finely ground.

For the past 20 years the writer has looked on red lead in linseed oil as one of the best primers for structural steel, and, when mixed with some other equally pure materials, as the best final coats. The first large contract under which he used this material was in 1897 on some bridges, aggregating about 5 000 tons, on which the following specification was used:

"Red lead in oil shall be of a good bright color and very finely ground. The pigment shall contain at least 95% of red oxide of lead; no sample will be accepted that contains more than 2% of foreign matter that is vitrified, or that contains metallic lead; or that when mixed with linseed oil and drying japan without grinding, and applied in a good body to a vertical surface of iron will not dry without running or separating."

The steel on this contract was erected promptly after fabrication, and no special opportunity was given to examine the wearing qualities of the primer, but it was undoubtedly the fact that there was difficulty in filling the specification, and, when filled, the resultant paint was of such a character that it could not be applied smoothly, but either ran or was streaky. It always had to be freshly mixed in order to work it at all. The general results, however, were good.

Within the past 5 years the following experience was obtained with about 27 000 tons of structural steel bridges divided into several contracts. Nearly all the work on each structure was fabricated at one time, and the conditions on the work were that only half could be erected at that time, the other half having to be stored. Linseed oil was the primer specified on the first lot of contracts and after storing over a single winter it was found necessary to clean and re-oil a very considerable quantity of the metal. The specifications on the remaining contracts were modified by requiring that the priming coat should consist of red lead of the same specification as given above. Experience showed that after storage of more than 2 years the metal was in good condition.

The red lead required at this time was not obtained without very considerable trouble. The samples first submitted to test showed 49.08 and 56.15% of red lead; they were rejected, and the paint-maker promised to do better. Three samples were then submitted, showing 77.66, 79.56, and 83.26%, respectively, and these were rejected. These rejections caused a storm of protest, and it was stated that it was impossible to obtain a higher percentage of red lead in a mixed paint. After

Mr. Wagner.

waiting some time the general contractor changed his paint man, and the next two samples showed 96.48 and 96.68%, respectively. The next three samples showed 98.11, 98.41, and 98.63%, and it is possible that if more paint had been needed the figures would have been higher. The paint when applied to the steel had a good bright color, and had none of the streaky appearance of the red lead of 1897. The color of such a paint is noticeably different from a paint with 75% of red lead. The fact that such paint with 94% and more of true red lead, as prepared by recent methods, will not set has not been noticed by the writer, but this has been probably because he has not followed up all the details. It is an important matter, and the manufacturers are to be congratulated on effecting this improvement, as well as the fact that it has greater covering value.

The writer was one of the railroad engineers who was requested by the Committee of the American Society for Testing Materials to examine the paints applied on the Pennsylvania Railroad Bridge over the Susquehanna River at Havre de Grace, and can testify as to the good appearance of the paints which contained red lead in the finishing coats. It is also of common knowledge that in many cases, when all paint has disappeared from structural steel, it is possible still to distinguish the shop marks of red lead where that paint has been used.

MEMOIRS OF DECEASED MEMBERS

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

WILHELM HILDENBRAND, M. Am. Soc. C. E.*

DIED FEBRUARY 21ST, 1908.

Wilhelm Hildenbrand, one of the most eminent designers and constructors of suspension bridges, was born on June 1st, 1843, at Karlsruhe, in the Grand Duchy of Baden, Germany. After receiving a classical education in the Lyceum of his native town, he entered its Polytechnic School, which was then the most renowned in Germany, having among its professors, Redtenbacher, one of the founders of scientific mechanical engineering, and Sternberg, equally prominent in scientific bridge design. After he was graduated in engineering and had passed the "Staats Examen" required for Government employment, he entered its service as Engineer of Highway Construction and as Inspector of rails at the rolling mills of Westphalia and Rhenish Prussia. After a year in the service of the State, he emigrated in 1867 to America.

His first position was as Draftsman in an architect's office, but he soon found employment with the late John A. Roebling, M. Am. Soc. C. E., who was at that time planning the construction of the Brooklyn Bridge. Under Mr. Roebling's directions, Mr. Hildenbrand made the first drawings of that famous structure, in the building of which he afterward took a prominent part.

During the delay caused by the initial difficulties of this enterprise he entered, as Assistant Engineer, the service of the New York Central Railroad where he was entrusted with the architectural design for the Forty-second Street Terminal Passenger Station in New York City, and with the construction of the great arched roof over the train-shed. Both structures were built in accordance with his plans and specifications, thus laying the foundation of his reputation as an architect and engineer. The roof truss had the largest span in the world at that time, and lasted until the entire reconstruction of the station required its removal.

In 1870, when the Grand Central Station was nearly completed, the actual construction of the Brooklyn Bridge began, and Mr. Hildenbrand was engaged by Washington A. Roebling, the Chief Engineer, as Principal Assistant Engineer. During Mr. Roebling's protracted illness, which confined him to his bed or room for nearly ten years, Mr. Hildenbrand made all the scientific investigations and mathematical

* Memoir prepared by Joseph Mayer, M. Am. Soc. C. E.

calculations necessary for the structure. He also made the architectural design for the approaches and had charge of the steel superstructure, which was designed, inspected, and erected under his direction.

In 1883, after the completion of the Brooklyn Bridge, Mr. Hildenbrand opened an office in New York as Consulting Engineer and, as Chief Engineer, built many suspension bridges in the United States and Mexico. He also built a truss bridge over the Ohio River at Wheeling, W. Va., which, like most of his work, is distinguished for its pleasing appearance.

In 1885 he submitted a design in the public competition for the Washington Bridge, and was awarded the second prize. Several features of his design were incorporated in this bridge as built.

In 1894 Mr. Hildenbrand did important work for the New York Chamber of Commerce which protested against the building of a pier near the center of the North River for a railroad bridge at that time projected by the New York and New Jersey Bridge Company. The President of the United States appointed a commission of five distinguished engineers to examine the feasibility of a single-span bridge across the river. Mr. Hildenbrand submitted a design, an estimate, and an argument in favor of a suspension bridge, and appeared before the Commission as the representative of the Chamber of Commerce. The Commission reported in favor of the feasibility of a suspension and against a cantilever bridge, which was the question at issue; Mr. Hildenbrand, therefore, carried his point.

In 1895 he became Chief Engineer of the reconstruction of the Covington and Cincinnati Bridge over the Ohio River. This was his most important and difficult independent work. The bridge is the third largest suspension bridge in the world, and was built originally by Mr. John A. Roebling in 1867, but had become inadequate for the increased traffic. Mr. Hildenbrand replaced the floor and the stiffening trusses with a wider floor and new stiffening trusses without interrupting traffic, and supplemented the old cables and anchorages by additional ones. The task of distributing the load between the new and the old cables was difficult, and required accurate calculation and delicate adjustment. It was evidently accomplished successfully; the new bridge is not only an adequate but a beautiful structure, and an ornament to the two cities. It was finished in 1899, to the satisfaction of his clients.

On the completion of this bridge, Mr. Hildenbrand went to Mexico, where he constructed a light suspension bridge, of about the same span as the Cincinnati and Covington Bridge, for the transport of silver ore from the mines of the Peñoles Company at Mapimi to the terminal point of a rack railway, built on the Abt system, which Mr. Hildenbrand had constructed in 1897.

As the representative of the Abt system of inclined rack railways, Mr. Hildenbrand, in 1889-1890, constructed the track of the Pike's

Peak Railway in Colorado, reaching an elevation of 14 214 ft., and furnished its locomotives.

In 1900, in the service of John A. Roebling's Sons Company, of Trenton, N. J., he became the Chief Engineer of the contractor for building the cables of the Williamsburgh Bridge. These cables, 50% larger than those of the Brooklyn Bridge, were built by him in one-third of the time required to construct those of the Brooklyn Bridge.

In 1904, he was appointed Consulting Engineer of the Westinghouse Electric Company, of Pittsburgh, and as such he designed the overhead structures for the electrification of the passenger traffic of the New York, New Haven and Hartford Railway, near New York City. He designed other and similar structures for the Westinghouse Company, acting as Consulting Engineer for this Company until his death.

In 1877 Mr. Hildenbrand published a treatise on "The Theory and Construction of Wire Cables," which is a standard work on the subject. In 1888 he published a book on "Underground Haulage of Coal by Wire Rope," which was awarded a medal and diploma of honor at the World's Fair of Chicago in 1893.

In 1895 he published in the German language a lecture on the history of suspension bridges from the earliest to the latest times. He also published many articles in the technical press, mostly referring to suspension bridges.

As an engineer and architect, Mr. Hildenbrand always showed good taste, and gave close and painstaking attention to all details. His extreme conscientiousness, which made him hesitate to delegate minor parts of his work to subordinates, was the only obstacle to his attaining a still more brilliant success than he achieved.

He had a very interesting and original personality, and was a true friend to many who were fortunate enough to make his acquaintance. He was liberal to a fault in his assistance to many who needed it. He was an enthusiastic admirer of Wagner, played his operas on the flute, and never missed attending their performance when opportunity offered.

He was married, in 1901, to Miss Hubbard, daughter of Judge Hubbard of Covington, Ky., who survives him.

Mr. Hildenbrand was elected a Member of the American Society of Civil Engineers on February 5th, 1902.

GEORGE BROWNE POST, M. Am. Soc. C. E.*

DIED NOVEMBER 28TH, 1913.

George Browne Post, the son of Joel B. and Abby M. Post, was born in New York City, on December 15th, 1837. He was educated at Churchill's Military School at Sing Sing, N. Y., and the Scientific

* Memoir prepared by the Secretary from information supplied by George B. Post and Sons.

School of New York University, from which he was graduated as Civil Engineer with the Class of 1858.

After his graduation, and during 1858, 1859, and 1860, he studied Architecture with the late Richard M. Hunt. In the latter year he formed a partnership with a fellow-student, Mr. Charles D. Gambrill, for the practice of Architecture.

During the Civil War, Mr. Post served in the Army for 4 months in 1862 and for 4 months in 1863, as Captain in the Twenty-second Regiment, New York Volunteers. At the first battle of Fredericksburg, he acted as Volunteer Aide on the staff of General Burnside, commanding the Army of the Potomac. Mr. Post was promoted to the rank of Major, Lieutenant-Colonel, and then Colonel of the Twenty-second Regiment.

After the War he resumed his professional career, and his partnership with Mr. Gambrill was dissolved. In 1905, with his sons, William S. and J. Otis Post, he formed the firm of George B. Post and Sons.

Among the buildings designed by Mr. Post during his long career, are the Prudential Life Insurance and the Mutual Benefit Life Insurance Buildings in Newark, N. J.; the Wisconsin State Capitol; the Cleveland Trust Company Building, in Cleveland, Ohio; and the Manufacturers' Liberal Arts Buildings at the Chicago Exposition in 1893. In New York City, he designed the buildings for the College of the City of New York; the New York Produce Exchange; the New Stock Exchange; the Pulitzer Building, and the Western Union Building, in Dey Street. He also designed the Equitable Life Assurance Society Building, and several well-known private residences.

Mr. Post was a Member of the Architectural League of New York, and served as President from 1893 to 1897, inclusive. He was elected an Honorary Life Member in 1912. He was a Fellow of the American Institute of Architects, of which body he was President from 1896 to 1899, inclusive. He was a member of the New York Chapter of the American Institute of Architects, and President in 1904; of the Fine Arts Federation of New York, and President in 1898. He was a Charter Member of the National Arts Club, and President from 1898 to 1905. He was a member of the Municipal Art Society, and served as Director from 1901 to 1909. He was a member of the Council of the National Sculpture Society in 1904. He was also a Member of the National Institute of Arts and Letters, the American Academy of Arts and Letters, the Province of Quebec Association of Architects, New York Academy of Sciences, American Geographical Society, National Society of Craftsmen, Public Art League, Archæological Society of America, National Geographical Society, and the Metropolitan Museum of Art. In 1907, he was appointed Honorary Corresponding Member of the Royal Institute of British Architects. He

was elected an Associate of the National Academy of Design in 1907 and an Academician in 1908.

In 1901, Mr. Post was decorated a Chevalier de la Legion d'Honneur of France. In 1908 he received the honorary degree of Doctor of Laws from Columbia University, and in 1910, he was awarded the Gold Medal of the American Institute of Architects.

When the Tenement House Commission, known as the Gilder Commission, was appointed by the New York State Legislature, he was made a member, and, in 1902, he was appointed a member of the Board of Commissions of the St. Louis Exposition by the Governor of New York.

Mr. Post was appointed, by the Secretary of State, as a delegate to represent American Architects at large at the World's Congress of Architects held in London, and, in 1906, the Secretary of Agriculture appointed him a collaborator of the Forest Service of the United States Department of Agriculture. In 1906, President Roosevelt made him a member of the National Advisory Board on Fuels and Structural Materials, to which Board he was reappointed in 1907, 1908, and 1909. In 1909, he was appointed a member of the Bureau of Fine Arts by President Roosevelt.

He was appointed a member of the Committee of Patronage to the Eighth International Congress of Architects in 1907, and in 1908 a Member of the Permanent Committee.

He was a member of the Expert Committee to appoint a sculptor and select a design for the Lafayette Monument erected in the courtyard of the Louvre in Paris.

In 1863, Mr. Post was married to Miss Alice M. Stone, daughter of William W. Stone.

He was a member of the New York Chamber of Commerce, the New Jersey State Chamber of Commerce, Century Association, Union Club, Cosmos Club of Washington, D. C., Lawyers' Club (Charter Member), and the New York Farmers Club.

Mr. Post was elected a Member of the American Society of Civil Engineers on September 2d, 1896.

CHARLES WALKER RAYMOND, M. Am. Soc. C. E.*

DIED MAY 3D, 1913.

Charles Walker Raymond was born at Hartford, Conn., on January 4th, 1842, and was the second son of the Reverend Robert R. and Mary A. (Pratt) Raymond. During his childhood his parents removed to Syracuse, N. Y., where he was edu-

*Memoir prepared by Dr. R. W. Raymond and Alfred Noble, Past-President, Am. Soc. C. E.

cated in the public schools and High School until 1857 when, his father becoming Professor of the English Language and Literature in the newly established Collegiate and Polytechnic Institute of Brooklyn, N. Y., the family moved to that city, and he entered that institution. As a child, he had been intensely interested in literature, but backward and awkward in mathematics. In the Polytechnic he came under the influence of Professor Richard Smith, a retired officer of the Engineer Corps (afterward President of Girard College), who was Professor of Mathematics; and, to the surprise of his family, he began to distinguish himself in that study. The strangest feature of this change was that he developed, under the inspiring touch of his brilliant teacher, not a previously unsuspected genius for mathematics, but a high ambition to conquer by persistent work the field which seemed so difficult. It was by hard work at every step that he acquired a thorough knowledge which placed him at the head of his class, and led Professor Smith to urge that he should seek an appointment as cadet in the United States Military Academy, on account of his unusual mathematical ability. In these days, when it is the fashion to educate boys mainly in the lines to which they show the earliest bent, this instance of training in directions not congenial is suggestive. We hear much about the subsequent failures of those who took the highest rank in school; but when that distinction is won, not through the easy superiority of genius, but by intense devotion to distasteful work, the man who wins it is likely to keep it always. This, at least, was the keynote of General Raymond's career, and the secret of his remarkable record of unbroken success through more than forty years of professional service.

Graduated from the Polytechnic in 1860, he was appointed in 1861 to the Military Academy, where he stood at the head of his class for four years. On his graduation, in 1865, he was immediately assigned to the Corps of Engineers with the full rank of First Lieutenant—skipping the rank of Second Lieutenant altogether. In his "furlough year" (1863), he had spent his leave of absence as an officer on the staff of Major-General Couch, by special appointment of the Secretary of War. General Couch commanded the Department of the Susquehanna, and Lieutenant Raymond's service with him in June and July covered the Campaign and Battle of Gettysburg.

From October 1st, 1865, to September 17th, 1866, he was Assistant to the Special Board of Engineers for improving the fortifications near Boston, Mass. He was then transferred to the Pacific Coast, where he served for a brief period as Assistant Engineer in the construction of the defences of Alcatraz Island, San Francisco Harbor, and then became Recorder of the Board of Engineers for the Pacific Coast. This position be held from December 28th, 1866, to March 3d, 1869, during which period he was promoted (March 1st, 1867) to be Captain

in the Corps of Engineers, and also conducted important operations at Lime Point, San Francisco Harbor, where he was Assistant Engineer for two periods—April 24th to July 7th, 1868, and November 5th, 1868, to March 3d, 1869. The work at Lime Point involved the removal of large masses of rock by heavy blasts. The interval between the two periods named was occupied with the reconstruction of Fort Stevens, at the mouth of the Columbia River, Oregon.

In 1869, after the purchase of Alaska by the United States, the American Fur Company, which had succeeded to the business of the Russian Fur Company, sent a small party up the Yukon River as far as Fort Yukon, a post of the Hudson Bay Company, to investigate the fur trade of the upper river and decide whether to establish an American station there. Captain Raymond was ordered by the Commanding General of the Department of the Pacific to accompany this party, for the purpose of making a reconnoissance of the lower Yukon, and determining astronomically the position of the meridian which constitutes the Eastern Boundary of that part of Alaska. Accompanied by one assistant and furnished with an astronomical field outfit, he joined the traders' party, which left San Francisco on April 6th, 1869, in a sailing brig, carrying on deck a small steam pinnace, and bound for Sitka, at which point his party was reinforced by one private soldier detailed for this service. Leaving Sitka on May 9th, the expedition, after many delays, reached the mouth of the Yukon, launched the little steamer, and proceeded in it up the river to Fort Yukon, a distance of, perhaps, 1,000 miles. During this trip, Captain Raymond and his assistant, relieving each other day and night, made a reconnoissance from which he afterward prepared the map of the lower Yukon which accompanied his official report and which was undoubtedly the best which had appeared up to that time. Arriving at Fort Yukon on July 31st, 1869, the traders' party soon ascertained that the fur trade of that region was not large enough to warrant the establishment of an American agency; and, as the freezing of the northern tributaries of the river was already threatening to make it too shallow for their steamer, they resolved to return at once, leaving Captain Raymond and his two companions to finish the astronomical work and make their way to the coast by themselves, but promising to hold the brig for them at the mouth of the river until a certain date. Establishing a field observatory, and observing the solar eclipse of August 7th, Captain Raymond determined the meridian boundary, proved that the British post was on American territory, and raised the American flag over it. (The post was immediately removed to the other side of the meridian.)

Leaving Fort Yukon on August 28th, his little party descended the river in a rude boat constructed by themselves—the Indians refusing to venture the voyage in their canoes at that season. This vessel con-

veyed them precariously as far as Anvik (about 500 miles from Fort Yukon and 500 miles from the sea), where it went to pieces. The remainder of the journey was characterized by hardship, exposure, and even starvation; and the explorers, exhausted and emaciated, reached the appointed rendezvous just as the brig was hoisting sail for San Francisco.*

From January 7th, 1870, to June 16th, 1871, he was Secretary of the Board of Engineers for Fortifications, etc., etc., of the United States; and from the latter date to August 23d, 1872, he commanded the Engineer Company at Willets Point, N. Y. On August 28th, 1872, he became Principal Assistant Professor of Natural and Experimental Philosophy at the U. S. Military Academy, and filled this position until February 27th, 1874, and again from August 31st, 1875, to July 1st, 1878—the interval being spent on special service in command of the U. S. Expedition to Northern Tasmania to observe the transit of Venus. From August 28th, 1878, to August 27th, 1881, he was Instructor in Practical Military Engineering, Signaling and Telegraphy, and during a part of that period served also as Superintending Engineer of Construction of the West Point Water-works, the Cadet Hospital, and the Cadet Barracks Extension. In the various positions mentioned, Captain Raymond spent more than seven years in actual service at the Academy.

During this period, he published an essay on Terrestrial Magnetism, which added to his already established reputation as a mathematician and physicist.

From August 30th, 1881, to January 13th, 1883, he commanded the Engineer Company at Willets Point. In January, 1883, he was placed in charge of river and harbor improvements, surveys, and coast defences in Massachusetts, and retained this position until February, 1886. The following condensed catalogue of his duties, compiled from the Annual Reports of the Chief of Engineers, will give some notion of their extent and variety: The protection and improvement of Boston Harbor, in which he established a practicable 28-ft. channel to the ocean; operations of similar character at the Harbors of Newburyport, Scituate, Plymouth, Provincetown, Lynn, etc., and Sandy Bay; studies and improvements of the Merrimac and Malden Rivers, and numerous other preliminary examinations, surveys, and projects. The most important of these works, from an engineering standpoint, was the improvement of Newburyport Harbor, at the mouth of the Merrimac, where Captain Raymond, through modifications of plan and method, secured, not only an increase of channel depth on the bar from 7 to 18.5 ft., but a saving in expense over the original scheme,

* Captain Raymond's official report, published as Senate Executive Document No. 12, of the Forty-second Congress, says little about the sufferings of his party, but they can be read between the lines. His health was permanently impaired.

which contemplated only a 17-ft. channel. His report on Sandy Bar (1884) contains a brilliant and novel discussion of the cross-section of a breakwater, and the anchorage capacity of a harbor, which contributed new ideas to engineering literature. On February 20th, 1883, he was promoted to be Major in the Corps of Engineers.

During his term at Boston, he served also for the greater part of 1883 and 1885 as Engineer of the First and Second Lighthouse Districts (covering the Coast of Massachusetts and Maine); and from October, 1883, to April, 1884, he superintended the removal of a wreck from Gloucester Harbor.

In February, 1886, he was ordered to take charge of levees and other improvements on the Mississippi River, from Warrenton to its delta, and from that position he was called, December 7th, 1886, to Washington, D. C., as Assistant to the Chief of Engineers. This office (which often made him temporarily Acting Chief of the Corps), he retained until January 26th, 1888, when he was appointed Engineer Commissioner of the District of Columbia—one of the three Commissioners constituting the government of the District. He served until February 1st, 1890, dealing, among other works of municipal engineering, with the difficult problem of electrical subways, concerning which his official report furnished a valuable theoretical and practical discussion.

From February 13th, 1890, to September 30th, 1902, he was (with the exception of two months in the latter year) continuously in charge of the defenses, harbor improvements, etc., at Philadelphia and in Delaware River and Bay. This work included the completion, on a novel plan and by a method designed by Major Raymond, and with great saving in both time and cost, of the now famous Delaware Breakwater which, disproving all the sinister prophecies of its early critics, stands unmoved after ten years of practical trial, a monument to his courage and originality as an engineer.*

The following sketch of his work in the Philadelphia District is compiled from the Annual Reports of the Chief of Engineers, from 1890 to 1902, inclusive.

For the first eight years of his tour of duty, the project for the Delaware River up to Philadelphia provided for a depth of 26 ft. at mean low water, and from Philadelphia up to Trenton for a depth of 12 ft. In the upper river above Philadelphia the principal obstruction to the 12-ft. channel was Kinkora Bar. At this point a dike had been built before he took charge. The natural depth was 7.5 ft. He suc-

* This work is described in the "Final Report of Lt.-Col. Charles W. Raymond, Corps of Engineers, Upon the Improvement of Delaware Breakwater," Reports of the Chief of Engineers, U. S. Army, 1899, Part II, p. 1346 *ff*. It is a significant circumstance that when Major Raymond took charge of it, in 1891, a plan had been already approved, in 1890, by the U. S. Board of Engineers, which he was expected to carry out; so that, in order to put his own conception into effect, he had to move that Board to recede from its own recently adopted scheme and adopt a new one, comprising features not supported by engineering precedents.

ceeded in obtaining greater depths, but the work done was not permanent in effect.

During these eight years he made annual examinations of the shoals in the river at Smith's Island Bar, Mifflin Bar, Schooner Ledge. Five Mile Bar, Bulkhead Shoal, Cherry Island Flats, Dan Baker Shoal, and other places. At most of the shoals and bars he obtained the projected depth of 26 ft.

Five Mile Bar is just above Philadelphia. It was improved by a dike and by dredging. Smith's Island was completely removed by dredging. Petty Island was partly removed. Ledges of rock were removed by blasting and dredging. Mifflin Bar was improved by dike construction and dredging. Schooner Ledge was deepened by rock removal. Cherry Island Flats was deepened by dredging. Bulkhead Shoal was deepened by the construction of Finn's Point dike. Dan Baker Shoal was originally planned to be deepened by a long dike from Reedy Island to Liston's Point, but this plan was later abandoned by reason of a decrease in the cost of dredging, and the channel was deepened by dredging alone.

In 1898 the condition of the river was good except at a few points. At Dan Baker Shoal the least depth was 16.5 ft. at low tide. In that year, a survey was made for the purpose of determining the possibility of still greater improvement, and on the basis of this survey a Board of Officers recommended a project for a channel from Philadelphia to Delaware Bay, 30 ft. deep and 600 ft. wide. Major Raymond started this improvement, deepening the channel to 30 ft. as rapidly as funds were made available. As the Delaware River is a silt-bearing stream which tends to obliterate artificial channels not placed exactly where Nature would place them, the improvement involves continual maintenance work. Even ten years after he had left the district, the work was still in progress, and it will always be continued as long as the river is used for commerce.

One of the great problems involved in this undertaking consisted in finding suitable places to dispose of dredged material. Major Raymond combined a dike for the improvement of Dan Baker Shoal with a plan for a disposal basin, making in mid-stream an artificial island about three miles long. The bulkhead was built, and the basin was so large that it has received dredged material for many years and is not yet full. This island is locally known as Raymond Island.*

*The following minute of the Executive Council of the Philadelphia Board of Trade shows the estimate placed on his work by that body:

"To the President and Members of the Executive Council of the Board of Trade:

"GENTLEMEN:

"Your Committee on the Improvement of the Harbor and Delaware and Schuylkill Rivers respectfully reports:

"That it has noted with regret the death of General C. W. Raymond, U. S. A., and in view of the services rendered by him to the city of Philadelphia during the twelve years he was in charge of this district as Engineer Officer, presents for your adoption the following minute:

"The Executive Council of the Philadelphia Board of Trade records this minute

In May, 1898, he became Lieutenant-Colonel, Corps of Engineers, and in May, 1901, a member of the U. S. Board of Engineers, of which, as a young Captain, he had been the Secretary, 31 years before. He remained a member of this Board until his retirement from active service in 1904.

During this period he completed the great work of an analytical index of the Reports of the Chief of Engineers from 1866 to 1900, inclusive. This book, in three volumes, is a model of intelligent and convenient classification, as well as comprehensiveness and accuracy.

It was in these later years of his life that some of his most important work was performed. As already observed, he served as member on many Boards and Commissions, reporting on fortifications, rivers, harbors of refuge, etc. Among these, the most noteworthy were: The Board to decide between San Pedro and Santa Monica Bay, for the location of a deep-water harbor on the coast of California; the Board to determine the maximum span for a suspension bridge, and especially for such a bridge over the Hudson River at New York; and the Board to determine the route and cost of a deep waterway from the Great Lakes to the Atlantic.

Of the two latter, he was the President. The report of the Bridge Board contained an analytical discussion of the Theory of Suspension Bridges, mainly prepared by him, a translation of which was subsequently used in Europe as a textbook of instruction. The Deep Waterways Board made careful surveys for a ship canal from Lake Erie to deep water on the Hudson River, below Albany, and, with the aid of maps furnished by the Engineer Corps of the Army for the chan-

upon the death of General C. W. Raymond, U. S. A., which took place after a lingering illness May 3, 1913.

"The city of Philadelphia owes a debt of gratitude to General Raymond for his intelligent and untiring efforts for the improvement of the navigation of the Delaware and Schuylkill Rivers and the removal of Smith's and Windmill Islands, which made possible a widened Delaware Avenue, and the building of wharves of such dimensions as to accommodate modern vessels.

"The work on the improvement of the harbor was prosecuted under his direction from the time the title to the islands was vested in the United States, under condemnation proceedings, May 29, 1890, until the completion of the readjustment of the harbor conditions, January 10, 1898, and during all that time he was responsive to every suggestion of the commercial and maritime interests looking to the early and successful termination of the work which has inured so greatly to the advantage of the city and port.

"It was under General Raymond (then Major) that the initial dredging for a 30-ft. channel, as provided by Act of Congress, March 3, 1899, took place, and was continued until he was relieved from duty at Philadelphia on July 20, 1901. He designed and practically carried to completion the great constructions belonging to the National Harbor of Refuge at the entrance of Delaware Bay.

"General Raymond's pre-eminent qualifications as an engineer were universally acknowledged, and his appointment as Chairman of the Commission to plan and construct the tunnel approaches to the New York Terminal of the Pennsylvania R. R. Co., was a practical recognition of his high standing in his profession; and the success of the undertaking furnished additional proof of his unrivaled technical skill and executive ability.

"The members of the Executive Council in adopting this minute, desire to express their high appreciation of the services of incalculable value rendered the port of Philadelphia during the twelve years General Raymond had charge of this district, and at the same time to tender his family their sympathy in the loss sustained by them.

"On motion, this minute was adopted by a rising vote and the Secretary instructed to send a certified copy to the family of General Raymond."

nels above Lake Erie, prepared detailed estimates for the whole line from the head of lake navigation. The report of the Board, which was the joint work of its members and assistants, was universally recognized as the most complete and thorough of its kind in the literature of engineering.

In January, 1904, he became Colonel, Corps of Engineers; and on June 11th of the same year, he was retired, at his own request, with the rank of Brigadier-General, U. S. A., after more than forty years of consecutive active service. The Government, however, still required him as one of its representatives in the International Congress of Internal Waterways, of which he was, from 1902 until his death in 1913, a member of the Council, Chairman of the American Section, an attendant at the meetings of the Congress, and a contributor to its Proceedings. The latest of these meetings was held in 1912 in the United States, and General Raymond would have been its presiding officer, had he been able to be present.

One of the most memorable labors of his life was the last. Already several years before his retirement, he had been permitted by the War Department, at the urgent request of the Pennsylvania Railroad Company, to act as Chairman of the Board of Engineers created by that Company to supervise the design and construction of the vast improvement contemplated by it in and around New York City, including the tunnels under the Hudson River, the East River, and the Borough of Manhattan; the great Pennsylvania Terminal in New York; and the terminals and yards on Long Island and in New Jersey. General Raymond was not an idle member of that supreme body; all important features of the plans and specifications were passed on by the Board, to the work of which he gave unremitting attention for more than eight years. The many studies and investigations carried out by him during that period were fruitful in determining the final design. Among the most important results of his special labors was the discovery of a minute diurnal rise and fall of the tunnel tube, under the influence of the tides. His recommendation that the tunnel should be left free to move, without any attachment of piles to resist either rise or fall, was adopted by the management of the Company, and has been vindicated thus far by experience. The great tube now adjusts itself freely to the changes in pressure of the material surrounding it, and its minute but practically irresistible movements do not affect its stability, in which, by reason of its immense weight, the effect of passing trains is likewise a negligible factor. The name of General Raymond worthily stands at the head of the list of engineers, on the great memorial tablet at the portal of the Pennsylvania Railroad Station in Seventh Avenue, New York City.

These labors were performed under difficulties which might well have discouraged a less intrepid spirit. General Raymond had lost

almost entirely, some thirty years before, possibly as the result of the hardships of his explorations in Alaska, the use of one eye; and, about 1900, the formation of a cataract in the remaining eye threatened him with entire blindness. Under this increasing disability (which finally reached such a point that he had to be personally led to and through the tunnels, and could examine drawings only with the aid of a strong glass, magnifying one spot at a time), he continued the active and efficient discharge of his duty as head of the directing Board of Engineers until, in 1910, its work was practically done, and his office in New York was closed. Even after that, in his seaside cottage near Atlantic Highlands, N. J., he dictated, at the request of the Pennsylvania Railroad Company, and under great difficulties of ever-growing blindness, a report of the work of his Board, which has been published by the Company and constitutes a memorable contribution to the literature of that branch of engineering.

Meanwhile, many successful operations (each partly, but not decisively, successful) had been performed on his eye, in which the obscuring film repeatedly gathered. In October, 1912, after months of total blindness, he went to Washington once more for another such operation, with more than usual expectation of permanent relief. The surgeons at Washington, however, discovered another and previously unsuspected trouble—an internal malignant tumor which forbade the expected operation and was itself beyond cure. There was nothing left on earth to him but hopeless darkness and cruel pain, which he bore with characteristic fortitude and patience until his death on May 3d, 1913. Conscious and serene to almost the last moment, he crowned with a heroic death a long, active, useful, and distinguished life, graduating at the end, as he had graduated at the Military Academy nearly half a century before, "at the head of his class." The Alumni of West Point may well be proud of his stainless and illustrious record.

Charles Walker Raymond was elected a Member of the American Society of Civil Engineers on June 1st, 1892.

BAIRD SNYDER, Jr., M. Am. Soc. C. E.*

DIED JULY 9TH, 1913.

Baird Snyder, Jr., was born at Pottsville, Pa., on November 21st, 1868. He was the third son of Baird and Edith Morris Snyder. The mother, now deceased, was a great-granddaughter of Robert Morris, so distinguished in the days of the American Revolution and a signer of the Declaration of Independence. His father, Baird Snyder, was the son of George Washington Snyder, one of the early pioneers of

*Memoir prepared by Mr. Frank A. Hill, Gen. Mgr., Maderia, Hill & Co., Inc., Pottsville, Pa.

the Anthracite Region, and the three generations have been prominent in the development and progress of mining in the district.

On his graduation from the Pottsville High School in 1885, Mr. Snyder entered the service of the Pennsylvania Railroad Company as Clerk in the office of the Chief Engineer.

In 1888 he joined the Engineer Corps of the Philadelphia and Reading Coal and Iron Company, and began the engineering career of which his friends and associates are so justly proud and which broadened in experience and grew in accomplishment until his valued life was suddenly closed.

In 1893, the late Joseph S. Harris, while President of the Lehigh Coal and Navigation Company, recognizing Mr. Snyder's ability, appointed him Assistant Superintendent of the mining operations of that Company at Lansford, Pa. Three years later he was made General Manager of the Company, and remained in this position until January, 1912.

The property which came under his management is one of the oldest and best in the Anthracite Region. The various adverse conditions which arise in the experience of the anthracite mine manager were all present during Mr. Snyder's administration at Lansford. The many difficulties of mining, pumping, ventilation, labor, fighting fire under ground, and countless others, were met with patience and self-reliance and were successfully overcome. Among Mr. Snyder's most marked qualifications for his position was his ability to handle men. No man had more loyal subordinates to aid him, and no men ever had a mort intrepid leader.

After nineteen years of active and aggressive work at Lansford, he resigned from his position with substantial expressions of confidence and regard from his Board of Directors and with the heartfelt regret of his subordinates.

On leaving the Lehigh Coal and Navigation Company, Mr. Snyder, as President and General Manager, organized the Locust Mountain Coal Company, for the purpose of operating an undeveloped area of coal land owned by the Stephen Girard Estate. He went into this enterprise with his characteristic fearlessness and vigor. He had completed his financial and working plans, and was in the midst of their early development with every confidence of success, when death came.

He had met and conquered the many engineering difficulties that had come to him in his old work, and was looking forward with pleasure to solving the new and less complicated questions which would meet him in opening an undeveloped territory of his own selection, but on July 9th, 1913, from injuries received in an automobile accident on the preceding day at Wapwallopen, Pa., this strong and virile life, filled with the promise of many more successful years, was cut off

"in the twinkling of an eye", leaving to his family and his many friends and professional associates only the memory of an active and well spent life, full of achievement; the record of an honest man, a good citizen, an able engineer—a record creditable to the membership of any engineering society.

Mr. Snyder was a man of splendid physique, of fine mentality, a reader, and a student. Positive, even to brusqueness, without fear, and a natural leader, he was also a devoted son, a loving husband, and a kind father. He is survived by his widow, Jennie Craig Romig Snyder, and two sons, Baird Snyder, 3d, and Robert Morris Snyder.

Mr. Snyder was elected a Member of the American Society of Civil Engineers on March 2d, 1904.

JAMES DYNAN NEWTON, Assoc. Am. Soc. C. E.*

DIED AUGUST 8TH, 1912.

James Dynan Newton was born at Oswego, N. Y., on April 17th, 1871. He entered Holy Cross College, Worcester, Mass., in 1887, and was graduated in 1891 with the degree of Bachelor of Arts. He taught sciences in the Roman Catholic High School, Philadelphia, for one year and then entered Sibley College, Cornell University, and received the degree of Mechanical Engineer in 1895. In the same year he was granted a Master's Degree from Holy Cross College.

After his graduation from Cornell he served as Special Apprentice in the New York Central Railroad shops at Oswego for five months. In December, 1895, after passing the examinations, he was appointed Cadet Engineer in the United States Revenue Cutter Service, and in 1896 he was promoted to Third Lieutenant of Engineers. He served in this capacity till 1902, when he was retired for disability incurred in the line of duty. He was in the Revenue Cutter Service during the Spanish-American War, and for a part of this time was Acting Chief Engineer of the U. S. S. *Hamilton*.

He was sent to the Marine Hospital at Fort Stanton, N. Mex., for treatment, and after leaving there was employed on mining development in New Mexico, practiced engineering independently, and, in 1904, was employed as Chainman and Rodman on the Atchison, Topeka, and Santa Fé Railroad. In August, 1905, he accepted the position of Assistant Professor of Civil Engineering in the University of Kansas.

The writer was in charge of the Department of Mechanics during the time of Professor Newton's service in the University of Kansas,

---

*Memoir prepared by Herbert A. Rice, Assoc. M. Am. Soc. C. E.

and, as a part of his teaching was in this Department, it gave good opportunity for observing his work.

In the Engineering Profession, no doubt, one of the greatest virtues is that of hard, conscientious labor, and this Professor Newton possessed in a marked degree. Entering a new field, he at once saw the necessity of careful preparation. He not only prepared himself for the work in hand, but spent many hours in the study of related subjects. His broad college training and his practical experience enabled him to present his subjects in an interesting and practical manner, and the writer always found his students enthusiastic in his praise.

At the end of his fourth year at the University of Kansas, he was elected Dean of the School of Engineering of Loyola University, Chicago, Ill. Here, his great capacity for labor stood him in hand. The Engineering School which had not been established, had to be organized, courses laid out, catalogue prepared, equipment purchased for a new building then in process of construction, and instructors engaged. This entire work fell to Professor Newton. Success attended his efforts, and, at the time of his death, the school was thoroughly organized and had enrolled many students in the new Department.

Professor Newton was an enthusiastic worker in the Roman Catholic Church, being one of the leading soloists in the church choir while in Lawrence.

He was married in 1906 to Miss Minnie Medaris, of Kansas City, who, with one child, survives him. They reside at Lawrence, Kans.

Professor Newton was elected an Associate of the American Society of Civil Engineers on September 5th, 1911.

ORLOFF LAKE, Jun. Am. Soc. C. E.*

DIED OCTOBER 21ST, 1913.

Orloff Lake, the eldest son of Duff G. and Mary Ida (Woods) Lake, was born at Baltimore, Md., on April 19th, 1883.

He was graduated from Tulane University with the degree of Bachelor of Engineering in 1905, and immediately thereafter entered the service of the Philadelphia and Reading Railway as Rodman, which position he held until April, 1906, when he resigned to accept the position of Transitman with the New York Central and Hudson River Railroad. He was soon promoted to Assistant Engineer, and had charge of office and field work on construction at Brewster; he also made surveys for

* Memoir prepared by J. F. Coleman, M. Am. Soc. C. E.

the relocation of the New Jersey Shore Line from Weehawken to Shadyside.

In January, 1908, Mr. Lake left the New York Central and joined the engineering forces of the writer as Assistant Engineer on general work in and near New Orleans. He remained in this employ until the summer of 1909 when he temporarily withdrew from the engineering field and transferred his activities for two years to the manufacturing business conducted by his father and uncle.

His love for his profession, however, led him to accept employment, in June, 1911, with the Barrett Manufacturing Company, and he was especially engaged in the Tarvia Department to co-operate with county and other engineers in the South who were devoting their time and talents to highway construction. Mr. Lake's education and training especially qualified him for this work, in which he continued with marked success until his sudden and untimely death.

Mr. Lake was a young man of exceptional attainments and brilliant promise. He was a tireless student and a most industrious worker, whose physical strength was without doubt often overtaxed by the tasks which he set for himself to perform. His exceeding modesty, amounting almost to diffidence, no doubt operated in retarding his professional progress during his brief life. His high ideals, sterling good qualities, and quiet forcefulness, however, were such that, as acquaintance with him ripened, confidence in and affection for him grew strong. In his death, the Profession and the Society have lost a most promising member; and in the zone of his acquaintance there is a void which may not easily be filled.

Mr. Lake was elected a Junior of the American Society of Civil Engineers on December 1st, 1908.

HENRY A. RICHMOND, F. Am. Soc. C. E.*

DIED MAY 10TH, 1913.

Henry A. Richmond was born in Syracuse, N. Y., on August 3d, 1840. He was the second son of Dean Richmond who, at the time of his death in 1866, was President of the New York Central Railroad Company.

Mr. Richmond was engaged in the grain business, as a commission merchant, at Buffalo, N. Y., and was well known among shipping circles on the Great Lakes. Later, he was connected with a lithographing business.

*Memoir prepared by the Secretary, from information supplied by C. M. Morse, M. Am. Soc. C. E.

After his retirement from active business, he became prominent in public affairs in Buffalo, as an "old-line Democrat". He was President of the Buffalo School Association, and was appointed by the late Grover Cleveland, then Governor of New York, as a Member of the first Civil Service Commission of New York State.

Mr. Richmond never married. He was a "wide traveler and a devotee of art and literature", and was liked and respected by all who knew him. He died at Los Angeles, Cal., on May 10th, 1913, and was buried in the Richmond Mausoleum at Batavia, N. Y.

Mr. Richmond was elected a Fellow of the American Society of Civil Engineers on July 7th, 1870.

AN INVESTIGATION OF SAND-CLAY MIXTURES FOR ROAD SURFACING.

By John C. Koch, Assoc. M. Am. Soc. C. E.

To be Presented March 4th, 1914.

Introduction.

The writer has been investigating the subject of sand-clay road construction for the past 2 years, for the purpose of establishing a sound basis for the selection of suitable materials for use in this cheap type of road. The materials are so cheap and distributed so abundantly that the writer is convinced that, if the Engineering Profession realized more fully the many advantages of such roads, there would be a much wider adoption of this type of construction.

The purpose of this paper is to set forth the results of the writer's study of these materials, both in the field and in the laboratory. This work was done under the auspices of the University of Georgia, a Good Roads Department having been established in the fall of 1911 for the purpose of carrying out a policy of University Extension work by offering free engineering assistance to the road officials of the State on highway and bridge work. The writer makes grateful acknowledgment of the facilities placed at his disposal by Chancellor

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

D. C. Barrow, of the University of Georgia, and C. M. Strahan, M. Am. Soc. C. E., for many helpful suggestions.

The growing demand for improved country roads at a low enough first cost to permit the construction of a relatively large mileage in counties of average financial resources has led, in many scattered sections of the United States, to an extensive adoption of the sand-clay type of construction.

Sand and clay are the most widely distributed materials in Nature, and, in suitable mixtures, yield a road-surfacing material which can be secured at low cost, because so readily accessible, and when properly built of intelligently selected material, it will render excellent service. Briefly stated, the advantages of sand-clay mixtures for road surfacing are:

(1) Low first cost,
(2) Low maintenance,
(3) No expensive machinery for construction or repairs,
(4) No skilled labor required.

Mixtures of sand and clay in proper proportions for road surfacing often occur in Nature, though good results can be secured by making artificial mixtures. The name "topsoil" has been widely used in Georgia and other parts of the South to indicate a natural mixture of sand and clay found on the surface of the ground over wide areas in the Appalachian region. Such natural mixtures, doubtless, are to be found in many other parts of the United States.

The principal advantages in using natural mixtures of the proper proportions, as compared with artificial ones are:

(1) The expense of mixing is eliminated,
(2) The natural mixtures become compacted in much less time,
(3) Repairs are more easily made, and new materials unite more quickly to the old.

The firmness of the wet sand road and the smoothness of the dry clay road are combined in the sand-clay type, and it remains of almost uniform smoothness throughout the year. It has been known for years in many localities that there were stretches of earth road that always kept hard and smooth, shed the water, and scarcely ever needed any repairs. Fig. 2 illustrates a section of natural sand-clay road near Center, Ga., which has been in use for 60 years. In such places

the surface soil has been found to contain the proper proportions of sand and clay, which, remaining undisturbed, has become compacted into a hard, water-proof surface.

There are many miles of sand-clay roads in Georgia which have cost less than $500 per mile for the surfacing in place. They carry heavy country traffic, and the repairs, during a period of 5 years, have not averaged $5 per mile per year. Considering the fact that the first cost of construction of such roads is less than the annual interest and maintenance charges on almost every other type which has been offered as an improvement on the earth road, it seems inevitable that wherever sand-clay materials are available and of suitable quality, it is the best type to use for the average country road.

Objects of the Investigation.

The writer's objects were to determine:

(1) The proper proportions of sand and clay in sand-clay mixtures to yield the best results, namely, durability in all weathers and absence of mud and dust;

(2) The limits between which the proportions of the two materials could vary without affecting seriously the quality of the resulting road surface;

(3) The effect of varying proportions of different sizes of sand in such mixtures;

(4) An approximate field method for the examination of soils, to determine their suitability for road surfacing.

Basis of the Investigation.

It will be readily seen that, to carry out an investigation along these lines, using artificially proportioned mixtures on short lengths of experimental road, would not only involve large expense, but probably would not be conclusive because of the difficulty of making artificial mixtures according to given proportions and maintaining such proportions. Then again, materials tracked on the experimental sections by the traffic would tend to affect greatly the value of such sections. For these reasons it was determined to base these studies on roads already constructed in various parts of Georgia, and in service from 1 to 5 years. In the course of this work the writer has traveled over 2 500 miles of roads, selecting various sections of sand-clay (including

"topsoil") roads which had been in use for some time and had worn well, and concerning which definite information could be secured as to materials used, methods of construction, and behavior of the road in all seasons of the year. From the best sections selected, samples of the road surfacing in actual service were chopped out with a hatchet for a depth of 4 in. in the wheel-tracks. Usually, a 5 by 5 by 4-in. sample was taken for laboratory study.

Samples were also taken from sections where such roads had not given entire satisfaction, on account of dust and mud. The writer has examined more than 900 samples, representing 48 counties, and comprising every typical sand-clay section of the State.

Properties of the Materials.

Clay.—The properties of a clay depend on the kaolin minerals and the impurities it contains. The kaolin particles may consist of prismatic crystals, thin plates or scales, or both. The effect of the impurities depends on the quantities of each and its fineness. Clays have no characteristic color; the pure are white, but they commonly occur as blue, gray, red, yellow, green, and purple, due to impurities.

All clays are derived from the weathering of feldspar, and the particles vary in size from small pebbles to such a minuteness as to defy measurement by the most refined methods. The finer particles readily go into solution in water, and even the larger ones are easily moved by running water. When removed in this manner and deposited at a distance, the deposits formed are called sedimentary clays. Those formed in place by the weathering of feldspar are called residual clays. In general, the sedimentary are finer grained and more plastic than the residual clays. The writer's experience has been that the latter make a harder and tougher mixture for road work than the sedimentary clays when combined with sand.

Clays vary greatly in density, plasticity, and size of grain. The important characteristics of this material for sand-clay construction are plasticity, shrinkage, and the property of "slaking". The plasticity is indicated by the ease with which a clay when wet to a certain extent can be moulded into various shapes which will be retained after the material has dried. The drying out of clay produces a shrinkage which seems to consolidate the particles into a compact mass. The extent of the shrinkage will depend on the fineness of the clay particles.

The coarser clays and those with much impurity (sand, etc.) shrink but little. The purer clays show a tensile strength of from 50 to 200 lb. per sq. in. when thoroughly dried; the coarser and impure ones have very little tensile strength. The most plastic clays resist water for a long time, but the others often crumble to pieces like quicklime. This rapid breaking down is due to the absorption of water by the pores of the clay, sometimes so quickly as to act with almost explosive suddenness. It is evident that a slaking clay would tend to break down rapidly into mud when exposed to rain and the puddling effect of traffic.

Sand.—Sand consists of particles of various sizes formed by the disintegration of the many kinds of rock in which quartz appears as an important component. As ordinarily found, the individual particles possess great crushing strength, as well as resistance to abrasion. These two qualities are of the greatest importance in the sand-clay combination.

Silt and Organic Matter.—In most of the natural sand-clay mixtures occurring in proper proportions for use directly as a surfacing material, the quantity of silt is usually from 3 to 8 per cent. The quantity of organic matter varies considerably, but, as it is light and easily washed out of the road by rains, its only effect seems to be to hold a certain quantity of moisture beneath the surface. Silt, if not in too large a quantity, seems to improve the road. In a few cases the writer has found silt and organic matter together, in quantities as great as 20% of the total sand-clay mixture, and yet the road was good. Probably in such cases a large quantity of water is held by this porous material and this aids in binding the sand particles together. Thus it appears that these materials are not necessarily harmful to the mixture.

Mixtures of Sand and Clay.

Whether natural or artificial mixtures are used, the properties of both materials which are best adapted to resist the weather and the wearing effect of traffic are utilized, and the unfavorable qualities of both are largely eliminated by using the two in proper combination. It has been shown that clay in the pure state shrinks as much as 10% when dried, and on being wet again will expand to an equal extent. By mixing clay with the proper quantity of sand, these contractions and expansions may be eliminated almost entirely. There-

fore, in a sand-clay mixture for road work, the sand, being held together by the clay, which usually more than fills the voids in it, takes the wear of the traffic in dry weather. In wet weather the water quickly drains off this almost impervious mixture, and the sand resists the cutting action of the traffic, although the clay may become puddled to a certain extent.

The writer is aware of the difficulties and intricacies introduced into the subject by the wide variety of clays available and their different characteristics. Nevertheless, he believes that the methods given in this paper, which have thus far proved highly satisfactory in the selection of sand-clay materials in many parts of Georgia, will be of general value wherever such materials are to be found. This basis of study of these materials has been of great service in choosing the best of a number of equally accessible deposits of natural sand-clay mixtures. It may with equal facility be used for determining in just what proportions the different materials should be used in order to get the best mixture possible out of the available local deposits where it is necessary to make artificial mixtures. Most clays contain varying proportions of sand, even when they appear to be almost pure. Clays are often sent in from the southern part of Georgia (where the surface soil is very sandy and it is desirable to lay clay on top of it in order to mix with it and form a sand-clay surface), and on analysis are found to contain as much as 60% of sand.

Laboratory Procedure.

Equipment.—So much that is useless is often purchased for laboratory equipment that the following list is given for the benefit of those who seek definite information on this subject. These have been found to give quite satisfactory service, and need not cost more than about $50.

One metric balance, 111-gramme capacity, reading to 0.01 gramme.
One metric scale, 2 500-gramme capacity, reading to 5 grammes.
One set of sand sieves, nesting, 8 in. in diameter, Nos. 10, 20, 40, 60, 80, and 100, with dust pan and lid, all brass.
Two steel moulds, brass lined, 1 in. in diameter, 4 in. long, with 5-in. close-fitting plunger.
One wooden mallet.
Six 300-cu. cm. evaporating dishes, porcelain.

Two Bunsen burners.
Several small tripods for burners.
Several iron wire mats, 4 by 4 in., for Bunsen flame.
Thermometer, 0° to 150° cent.
Six, 2-quart, enameled milk pans for baths, etc.

The evaporating dishes should be Royal Berlin porcelain, as this is the only kind that the writer has found satisfactory.

Separation of Materials.—Samples are usually taken in several parts, so as to enable one to determine to what depth the material may be used. In some cases a sample may be in three or more parts, being 4-in. layers taken in succession from the same hole, each being kept separate from the others. After analyzing each part of a sample separately, the composition of the top 4, 8, 12, or 16 in. can be determined easily. This gives a clear idea of the value of the material and of the greatest depth to which it may be excavated.

The essential objects of the laboratory examination are to ascertain:

(1) Relative proportions of sand and clay,
(2) Physical analysis of sand,
(3) Physical properties of the mixture of sand and clay,
(4) Determination of presence of other material which might prove detrimental,
(5) Physical properties of the clay.

To attain these objects, the following steps are necessary, in the order of their importance, and to reduce the laboratory work to a minimum:

(1) Separation of sand and clay,
(2) Mechanical analysis of the sand content,
(3) Slaking test on cylinder of sand-clay,
(4) Examination for mica and feldspar,
(5) Slaking test on clay cylinder.

1.—Separation of Sand and Clay.—The sample to be examined is first dried thoroughly in the air; then it is screened through a No. 10 sand sieve (10 meshes per linear inch), lumps and clods being pulverized with a wooden mallet beforehand. All coarse materials caught on the No. 10 sieve are considered arbitrarily as gravel, and all smaller materials are taken as the sand-clay portion. Pieces of grass, roots, etc., are discarded, of course, before weighing the two parts of the

screened sample. The material held on the No. 10 sieve is regarded as being much the same as the broken stone in a concrete mixture, and the sand-clay as the cement and sand portion constituting the mortar in such a mixture.

The part of the sample passing the No. 10 sieve is then examined as follows: By successive quartering, about 150 grammes are taken and dried in the air bath at 100° cent. to constant weight. This may often be dispensed with, and the sample merely air dried. Then 100 grammes of this material are weighed and placed in a porcelain evaporating dish; water is added and the soil rubbed well until the clay particles are in suspension. The clay in suspension is then carefully poured out and more water is added; the process is repeated until there is faint or no coloration of the water when the residue is stirred up. By washing the materials properly, practically all the organic matter, silt, and clay are removed, and only the sand particles are left, with possibly some mica and feldspar.

2.—Mechanical Analysis of the Sand.—The moisture in the residue in the evaporating dish is then evaporated, leaving the sand dry and ready to be screened. After weighing the sand it is screened through a nest of five sieves having 20, 40, 60, 80, and 100 meshes per linear inch. The weights of sand caught on each of these sieves are determined, and a curve is plotted showing the weights as ordinates and the sieve sizes as abscissas, based on 100% for the total weight of the mixture of sand and clay. Thus the weights in grammes show as percentages of the total. Fig. 1 was prepared in this way, and shows graphically the sand analyses of a number of samples.

3.—Soil Slaking Test.—A test cylinder, 1 in. in diameter and 3 in. long, is made of the material passing the No. 10 sieve by wetting it sufficiently to make a very stiff paste and after working it thoroughly together, placing it in a metal mould, using a tight-fitting plunger to compact the material as much as possible by tamping with a mallet. This cylinder should be dried to constant weight in the air bath at 100° cent. When entirely cooled it should be immersed completely in a glass jar of water at a temperature of 21° cent., and the time noted in which it disintegrates completely. Disintegration is assumed to be complete when the cylinder has broken down until the material is standing approximately at its natural slope of repose.

In sand-clay mixtures which have given satisfactory service, the

time to disintegrate completely may vary from 2 min. to nearly 1 hour; usually, it will be from 5 to 20 min. This test will give a fairly good idea of the resistance of any sand-clay mixture to the action of water, and, for purposes of comparison, is made more easily and

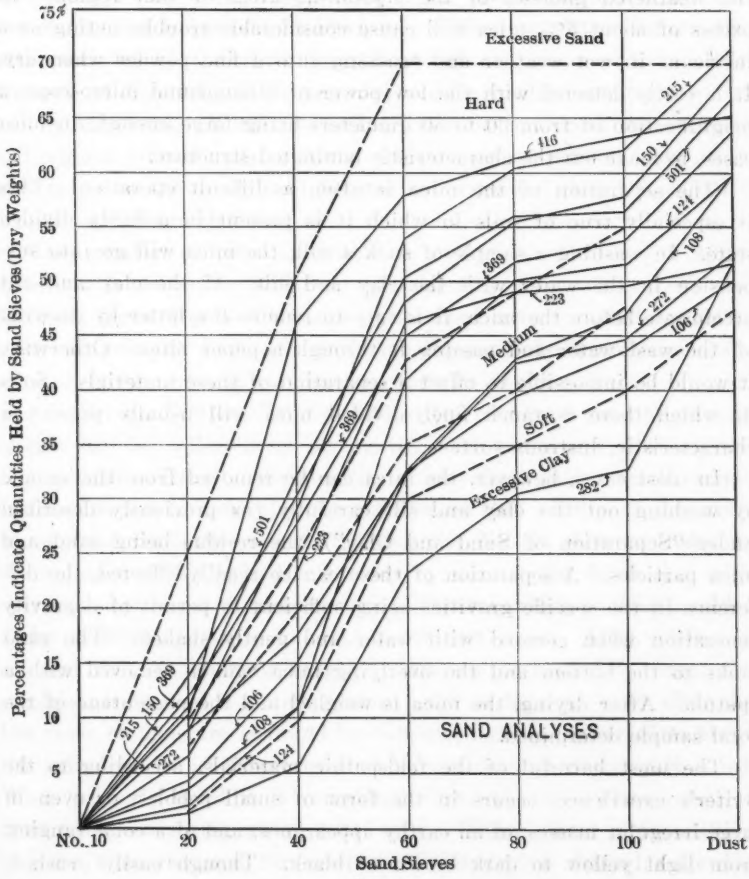

FIG. 1.

quickly than that to be described for the slaking of clay alone. The most durable mixtures, in general, are those which take longest time to disintegrate. Mixtures containing a coarse, flaky clay may hold their shape for several days before breaking down completely, but this is not a frequent occurrence.

4.—Tests for Mica and Feldspar.—Mica is easily recognized, and its presence need occasion no alarm unless it exceeds 5% of the total sand-clay sample. This is especially true of the Southern Appalachian region, where mica is often associated with the coarser sands, as in the weathered gneisses of the crystalline areas of that region. In excess of about 5%, mica will cause considerable trouble, acting as a lubricant in wet weather and crushing into a fine powder when dry. It is easily detected with the low power of a compound microscope, a magnification of from 30 to 50 diameters being large enough, in most cases, to make out the characteristic laminated structure.

The separation of the mica is often a difficult operation. This is especially true of soils in which it is present in a finely divided state. In washing a sample of such a soil, the mica will go into suspension in the water with the clay and silt. If the clay and silt precipitate before the mica, it is easy to remove the latter by drawing off the wash-water and passing it through a paper filter. Otherwise, it would be impossible to effect a separation of these materials. Soils in which there is much finely-divided mica will usually present a characteristic, lustrous surface.

In most cases, however, the mica can be removed from the sample by washing out the clay and silt carefully (as previously described under "Separation of Sand and Clay"), the residue being sand and mica particles. A separation of these can be readily effected, the difference in the specific gravities being sufficient to permit of a gravity separation when covered with water and gently shaken. The sand sinks to the bottom and the overlying mica can be removed with a spatula. After drying, the mica is weighed and the percentage of the total sample determined.

The most harmful of the feldspathic materials, according to the writer's experience, occurs in the form of small pebbles, or even in large irregular masses, of an earthy appearance, and of a color ranging from light yellow to dark brown or black. Though easily crushed, it will generally have more coherence than the clods of earth or clay in the sample. Therefore, the larger pebbles can be separated by screening the dried sample through the No. 10 sieve. If pebbles of other material are also found, the difference in color will permit of a separation. The feldspathic materials passing the No. 10 sieve, together with the sand, clay and silt, will be left with the sand, as a

residue after washing out the other materials. Separation of the feldspar can then be made in the manner described for mica. If this material occurs in greater proportions than about 8% of the total sample, by dry weight, the road surface will cut and wash easily. This is a figure based on actual experience with a few roads, and is probably subject to modification, depending on the characteristics of the other components of any given sample. The presence of fine feldspathic material will be readily apparent in the soil cylinder test. When the soil cylinder is immersed the feldspar will almost immediately go into solution or suspension, and in a minute or so the water will become so discolored that the cylinder cannot be distinguished.

The number of cases in which a separation of either of these materials is advisable will vary considerably. In the writer's experience, about 6% of all samples examined were analyzed quantitatively for mica or feldspar. Although the methods described are approximate, they have given very satisfactory results.

5.—Slaking Test on Clay Cylinder.—The clay from the 100-gramme sample can be collected by saving the wash-water and allowing the clay to settle. Usually, the quantity of clay from such a small sample is not sufficient to make the test cylinder, so that additional clay must be removed from the material passing the No. 10 sieve to make up the cylinder. This cylinder is made by mixing the dried clay with only sufficient water to make a very stiff paste, which is then moulded under sufficient pressure to make a compact mass. After drying in air and then to constant weight in the air bath at 100° cent., the specimen is kept at that temperature until at least an hour after the last trace of moisture is found by condensation on a glass plate above the cylinder. It is important that the cylinder be thoroughly dried. When properly dried it is completely immersed in a glass vessel of proper size containing water at 21° cent. The character of the slaking and the time required for complete disintegration depend somewhat on the temperature of the water, and the freedom from moisture of the dried cylinder, so that, for a comparison of results, all specimens should be thoroughly dried and the water for the test brought to the same temperature in each case.

The slaking of clay is similar to that of quicklime, except that the action is entirely physical and not chemical. The time and character

of the slaking give an idea of the value of the clay as a binder in the sand-clay mixture. In clays which have been separated from samples taken from road surfaces which have proved satisfactory, the time for the clay cylinder to disintegrate completely varies from 2 to 20 min., the average being about 4 min. The degree of disintegration of the clay may vary from finely divided particles to flakes almost $\frac{1}{8}$ in. long. In general, the coarser the particles the better the indication for suitability for road work. Clays which disintegrate completely in less than 2 min., may be regarded with some suspicion, but need not necessarily be rejected entirely, unless the sand analysis and the soil cylinder also give poor tests.

Typical Examples, with Analyses and Road Histories.—It is thought that a few characteristic cases from actual practice may be of interest. In Table 1 is given a list of the samples, with the locality from which each was taken. Table 2 shows the sand and clay analysis, based on the dry weight of the sample, the total weight of each sample being taken as 100%; all sand percentages are based on this.

NOTE.—Sand No. 10 is based on gross sample = 100%, and includes all gravel. Remaining portion of table is an analysis of material smaller than No. 10.

Fig. 1 shows a graphic analysis of these samples, with the sand analysis in detail. This diagram also gives, graphically, the limits between which the writer classifies his samples, basing such classification on the sand analysis as well as the clay content, both of which are shown.

The limiting curves separating the analyses into four groups are based on the writer's experience, and are given with full confidence in their utility. They are of sufficient accuracy to be of considerable

service in classifying sand-clay mixtures properly and quickly, and arriving at a reasonable approximation of their value as road material. Quite often it will be found that the sand analysis alone may show that the material is unsuitable and much time may be saved that might otherwise have been lost in continuing the examination and applying other tests.

TABLE 2.—ROAD HISTORIES.

Sample Numbers Refer to Corresponding Numbers in Table 1.

Sample No.	County.	Road.	Sample taken.
106	Bulloch	Statesboro-Savannah	6.7 miles south of Statesboro.
108	Dougherty	Albany-Thomasville	4.3 miles south of Albany.
124	Sumter	Americus-Albany	6.0 miles south of Americus.
150	Clarke	Athens-Danielsville	3.2 miles northeast of Athens.
215	Dougherty	Albany-Thomasville	2.1 miles south of Albany.
223	Richmond	"Augusta gravel" from pit.	
272	Habersham	Clarkesville-Cornelia	1.2 miles from Clarkesville.
369	Clarke	Athens-Barnet Shoals	4.3 miles from Athens.
416	Hall	Thompson's Bridge	2.0 miles north of Gainesville.
501	Clarke	Athens-Whitehall	2.0 miles from Athens.
282	Decatur	Bainbridge-Jacksonville	7.0 miles south of Bainbridge.

The analyses falling in the group marked "Hard" will usually give a durable, hard road surface which wears exceedingly well, and, after consolidation, can be cut only with great difficulty by a road machine, if at all. Analyses in the "Medium" group will give an excellent, smooth, hard, surface, but one which may cut a little in protracted wet weather. Such a surface is too hard to attempt to shape up with a road machine, except after very long wet periods. This may be taken as a sort of "average" quality of sand-clay.

The analyses grouped in the "Soft" class give a surface which is much superior to the ordinary earth road, but which will tend to be somewhat dusty in dry weather and will cut easily and tend to wash in wet weather. Material of this type requires re-shaping, after every heavy rain, with a road machine or drag. The class "Very soft" comprises all materials which have too large a clay content to give a satisfactory road surface; they should not be used at all, as the expense is scarcely warranted for the kind of road surface that can be obtained with it.

The writer's method is to make the separation of sand and clay and then the mechanical analysis of the sand. If the material shows up poorly in the sand analysis, the further tests are not made, unless,

after making a similar examination of all other available materials, it appears to be the best available. Each case is a special problem in economy, and a study of each will indicate the proper method of using local materials if they can be used at all.

Road Histories.

The following is a brief history of the various roads, samples of which were analyzed and the results presented in Table 1, and graphically in Fig. 1:

106.—Bulloch County.—Had been in service 3 years at time sample was taken. Excellent, hard, smooth surface, but occasionally dusty in prolonged dry seasons. Softens in wet weather and cuts badly then. Re-shaped after heavy rains with light drags. Artificial mixture.

108.—Dougherty County.—Good smooth surface in dry weather. Road in service about 3 years at time sample was taken. Softens and washes in heavy rains. This material, found about 2 ft. below natural surface, is used without addition of other material.

124.—Sumter County.—Very good, smooth surface, but softens and washes badly in wet weather. Re-shaped with light drags after even moderate rains. This is generally true of all the roads in this county, the materials available being very similar in mechanical analyses. Natural mixture occurring 2 ft. below surface.

150.—Clarke County.—Road in use 4 years, with practically none but the very lightest repairs, when sample was taken. Cost of maintenance, as given by superintendent, averaged less than $5 per mile per year. Very little dust, firm, hard road surface throughout the year, though freezing and thawing might at times soften the crust for a depth of an inch or so. No re-shaping with road machine possible, on account of the hardness of the compacted material. This seems to represent the best and most durable type of sand-clay combination yet found in Georgia. Natural mixture found as topsoil of cultivated fields.

215.—Dougherty County.—Road in use about 3 years at time sample was taken. Good hard surface, softens but little in wet weather, and wears well, keeping good shape. Too hard to re-shape by dragging. Few repairs. Natural topsoil.

223.—Richmond County.—Reports of roads on which this material had been used indicate that it produces very satisfactory results. This

FIG. 2.—NATURAL SAND-CLAY ("TOPSOIL") ROAD, NEAR CENTER, GA. IN USE ABOUT 60 YEARS.

FIG. 3.—NEAR THE SAME PLACE AS SHOWN BY FIG. 2. NEW ROAD ON THE RIGHT.

FIG. 4.—TYPICAL SAND-CLAY ROAD IN THOMAS COUNTY, SOUTHERN GEORGIA.

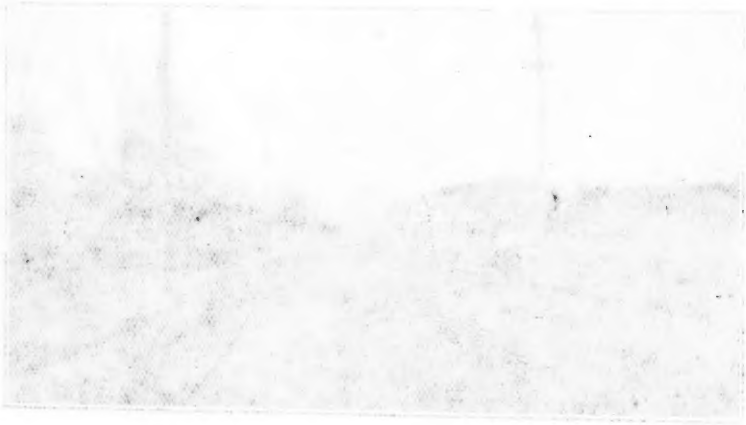
FIG. 6.—CENTER ROAD, CLARKE COUNTY, GEORGIA. CLAY ROAD AT LEFT. NATURAL TOPSOIL ROAD AT RIGHT.



material is shipped by rail for road construction for distances as great as 100 miles. The analysis in Table 1 indicates that this is really a low-grade gravel rather than a sand-clay mixture. Yet it is interesting to note that the mechanical analysis of the portion of this material smaller than No. 10 mesh agrees very well with the mechanical analysis of the better classes of sand-clay mixtures which, with very small gravel contents, have given results almost as good. The mechanical analysis is shown on Fig. 1, considering only the portion smaller than No. 10 mesh. This material is dug from a large pit near Augusta, and has been in use for many years.

272.—Habersham County.—The road from which the sample was taken had been in use for about 8 months. The surface is hard and smooth, and softens but little in wet weather. This material was selected by the writer after sampling a large number of local deposits. Haul, about 2 000 ft. Cost in place, for 16-ft. width of surfaced roadway, about $500 per mile. Local officials, after using macadam at about $6 000 per mile, pronounce this a better road than macadam, even if initial cost and maintenance were equal. Local natural mixture of sand-clay from topsoil of cultivated field.

369.—Clarke County.—Built about 3 years at time sample was taken. Hard, durable surface. Few repairs. Too hard to drag. Experience quite similar to that of No. 150. Natural topsoil sand-clay mixture, obtained from nearby cultivated fields.

416.—Hall County.—In use less than a year. Replaced macadam road that cost $6 000 per mile, and gives better satisfaction than the macadam. Cost $350 per mile for 16-ft. width of roadway. Material natural topsoil from nearby cultivated field.

501.—Clarke County.—Road from which sample was taken had been in use about 3 years. This road was surfaced with a very thin layer of natural topsoil from adjoining fields, so that, after being compacted by traffic, its thickness was about 3 in. In seasons of prolonged wet weather traffic occasionally cuts through and mud-holes are formed. The material is excellent, but has not been used in sufficient quantity to give the best results. A comparison of its mechanical analysis with that of other samples indicates its high quality.

282.—Decatur County.—The road from which this sample was taken had been in use about one year. This is practically no improvement over the ordinary earth road, as the sand content is so low as

to be of no value in improving the quality of the road surface. It is very dusty in dry and very muddy in wet weather, after the traffic has been on it a few days. As difficult to maintain as an ordinary earth or clay road. Material used was taken from adjoining fields at a depth of 2 ft.

Table 3 is a summary of the road histories and the corresponding analyses, for comparison. For simplicity, the portion of the sample larger than No. 10 will be considered apart from that smaller than No. 10.

Effect of No. 10 Sand.—Comparing Sample No. 106 with the others, it is found to contain a larger quantity of No. 10 sand than any of them, with the exception of No. 223. No. 223 is really a low-grade gravel, and is discussed in a succeeding paragraph. The history of No. 106 is not nearly so satisfactory as that of the remaining samples, except Nos. 108 and 282. Sample No. 108 is slightly more satisfactory than No. 106, and No. 282 is practically an earth road. Furthermore, Samples Nos. 124, 215, and 272, which contain no No. 10 sand at all, have given much more satisfactory service than No. 106.

It has been found by the writer, in samples of gravel and chert roads (Augusta gravel being a typical material), that the part larger than No. 10 varied considerably in the few samples examined, although the composition of the part smaller than No. 10 was fairly constant in the proportion of sand to clay. The gravel part of any sample may reasonably be taken as an approximate measure of the durability of a road built with such mixtures. In addition, if a sample has a considerable proportion of gravel and is deficient in sand, the presence of the gravel will largely offset such defect.

From the foregoing it is clear that the effect of No. 10 sand on a mixture may be, either that of making up a deficiency of sand in the portion of the sample smaller than No. 10, or to increase durability when there is no deficiency of sand. Hence, its effect depends largely on the analysis of the portion of the sample smaller than No. 10.

Material Smaller than No. 10.—Based on their histories, the samples of Table 3 may be divided into four groups:

1. Ordinary earth, No. 282;
2. Inferior sand-clay, Nos. 106, 108, 124, and 272;
3. Superior sand-clay, Nos. 150, 215, 369, 416, and 501;
4. Low-grade gravel, No. 223.

Notes:—*Data for No. 223, based on roads built near Augusta, Ga.
No. 272, Road in use 8 months at time of report.
No. 416, Road in use 7 months at time of report.
No. 282, practically an earth road.

Considering only the second and third groups, the sand-clay analyses may be condensed into Table 4.

TABLE 4.—COMPARATIVE ANALYSES OF SAND-CLAY GROUPS.

	Inferior Sand-Clays.		Superior Sand-Clays.	
	Limits.	Average.	Limits.	Average.
Sand total	52.6-60.0%	56.3%	63.8-71.5%	67.6%
Sand Nos. 20-60	32.3-41.0%	36.6%	45.0-57.9%	51.4%
Sand No. 100 and dust	10.0-17.0%	13.5%	4.1-13.8%	8.9%
Clay total	40.0-47.4%	43.7%	28.5-37.0%	32.7%

The principal differences between the two groups are:

1. The total sand content in inferior mixtures averages about 11% less than in superior mixtures;
2. The total quantity of sand from Nos. 20 to 60, in the former averages 15% less than in the latter.

Effect of Size of Sand.—Although the quantity of clay is nearly the same in Nos. 106 and 282, the former is a much more durable material. Roads built of the former withstand severe rains far better than those built of the latter material. To account for this, it must be remembered that the analysis of the whole sample of No. 106 is: Sand No. 10, 6.5%; sand No. 20 to dust, 43.7%; clay 43.8 per cent. The difference in the clay content is only about 4% in the two samples, which seems too little to account for the great difference in their conduct. By reference to the sand analyses of the two samples, it is seen that No. 106 contains nearly three times as much of the No. 20 and No. 40 sands, nearly the same quantities of Nos. 60, 80, and 100 sand and only one-third as much dust, as No. 282. This considerable difference in the ratio of coarse to fine sands explains, in large measure, the difference in the durabilities of the two materials.

CONCLUSIONS.

A study of nearly a thousand analyses, in the laboratory, and a comparison of the results attained with such materials in actual road construction, have led the writer to formulate the following tentative working rules for examining sand-clay mixtures and as a basis for making up proper combinations for artificial mixtures:

(1) The total relative sand content, disregarding the size of the sand grains, is no criterion of the value of the material.

(2) The sand smaller than No. 60 is of little value in the mixture, that smaller than No. 100, except in very small quantities, is detrimental.

(3) The greater the proportion of coarse to fine sand the harder and more durable will the road surface be.

(4) For the best possible results with sand-clay mixtures, the sand smaller than No. 10 and larger than No. 60 should not be less than 45% nor more than 60%, by dry weight, of the entire sample. In addition, the sand smaller than No. 10 and larger than No. 60 should be composed of about equal parts of Nos. 20, 40, and 60. The total sand content should in no case exceed 70% by weight, of the total sample.

(5) Test cylinders of the sand-clay mixture, 1 in. in diameter and 3 in. long, should, when thoroughly dried in air bath at 100° cent., take at least 2 min., when immersed in water at 21° cent., to crumble down to the natural slope of the material, and preferably should take 6 min. If the cylinder fails in this test, it should be regarded with suspicion. If the sand analysis is poor and the cylinder test is also poor, the material is not worth using.

(6) Test cylinders, made from the clay removed from the sample, 1 in. in diameter and 3 in. long, should take at least 2 min. to crumble down to the natural slope of the material, when immersed in water at 21° cent. If it fails in this test, but passes the test of the preceding paragraph, it may be used, but it indicates a poor quality of binder.

Approximate Field Method for Examining Sand-Clay Mixtures.

As a rapid aid in forming a judgment in the field as to the value of any mixture, the writer offers the following: A buggy inspection is made of the natural soil on both sides of the road to be improved. Samples are taken wherever the surface appearance seems to indicate favorable material. These samples are placed in paper bags, with notes of the location, etc. The samples are usually taken for a depth of 4 in. Each sample can be dried sufficiently by spreading out in the sun in a thin layer. When dried, the sample may be placed in

a No. 10 sieve and screened, and note made of the relative weights of the residue on the screen and the finer material. Then 100 grammes of the part passing this screen are weighed and placed in an evaporating dish. By careful washing, in a few minutes practically all the clay may be washed out, and is rejected. The sand residue is then dried with an alcohol flame, and weighed. It is then placed in a No. 20 sieve nesting over a No. 60 sieve. By screening the sand thus it can be quickly separated into three sizes: No. 20, between Nos. 20 and 60, and smaller than No. 60. These three portions can be weighed, and from this information a very good idea may be obtained of the comparative value of the material, without additional tests.

The proportion of the material coarser than No. 10 indicates the proportion of gravel present. The separation into No. 20 size and between Nos. 20 and 60 shows practically into what class the mixture would fall, and the portion smaller than No. 60 would indicate the quantity of almost worthless material in the mixture. By using Fig. 1 a very good idea of the quality of the sample would be gained.

Methods of Sand-Clay Construction.

There are two general methods of construction in use, one in which the natural mixture of sand and clay is used, the other in which an artificial mixture is made by using two or more materials which are mixed by plowing together, puddling, etc.

Construction with Natural Mixtures.—The method which the writer believes is simplest, and produces excellent results, is as follows: Natural mixtures of the proper proportions of sand and clay may be found as the natural topsoil of cultivated farms, or may be found below the surface at various depths. The material comprising the topsoil of cultivated land, when composed of the proper combination of sand and clay, has probably been more thoroughly weathered and therefore is less likely to wash and disintegrate when placed on the road. Cultivation has also produced a more thorough and complete mixture of the two materials.

In the northern half of Georgia the topsoil in large areas, especially on the tops of ridges, for a depth of from 6 to 12 in., is found to be an excellent sand-clay mixture. In the southern half of Georgia, a natural mixture of sand and clay is often found at a depth of from 2 to 5 ft. below the surface. Such material is not usually very well

JEFFERSON ROAD, CLARKE COUNTY, GEORGIA.

FIG. 7.—TOPSOIL PLACED SIX HOURS BEFORE PHOTOGRAPH WAS TAKEN.

FIG. 8.—TOPSOIL AFTER ONE WEEK OF TRAFFIC, WITH THREE HEAVY RAINS.

FIG. 9.—JEFFERSON ROAD AFTER SIX MONTHS OF TRAFFIC, OCTOBER, 1912, TO MARCH, 1913. TWELVE HOURS AFTER HEAVY RAIN.

weathered, so that, after being placed in the road, a certain quantity is found to wash out quite readily with the first few rains.

In either case the method of construction may be the same. The sub-grade of the roadway is brought to a level or slightly convex cross-section. The sand-clay is then placed in a continuous layer, from 10 to 12 in. thick, the material being spread as fast as delivered and not dumped in piles here and there. This layer is spread for a width of 20 ft. for a nominal 30-ft. roadway. After a sufficient quantity has been placed in this manner, an ordinary road machine is drawn along the ditch line, cutting about 4 in. deep at the outside, and the blade is set so as to cast the material from the ditch against the edge of the sand-clay layer. In this way a shoulder is built up against the sand-clay to hold it in place. This also shapes the ditch. After both sides have been thus shaped, the road machine, in successive passages, rounds up the cross-section of the sand-clay so as to give proper crown to the roadway and a smooth line from the crown to the ditches. As soon as the road is shaped, traffic and the construction teams begin to compact it, and it rapidly becomes consolidated without the use of a road roller. As the consolidation progresses, ruts are formed, and they should be filled and a proper cross-section maintained by the occasional use of the road machine for a period of about 2 months. Unless this is done, the road surface will become rutted and rough, and eventually compacted with a concave crown which will prevent proper drainage. After the material has been consolidated into a hard mass, the difficulty of securing a good cross-section is largely increased.

The cross-section which seems to have given the most generally satisfactory results is a parabolic form with a crown of $\frac{1}{2}$ in. per ft., that is, for a roadway surfaced for a width of 20 ft., the crown would be 5 in., and the height of the center of the road above the ditch (for a road having a width of 30 ft. between ditches) would be 7.5 in. With steeper crowns than this it has been found that the surface cuts into a series of parallel ridges running from the wheel tracks to the ditches and making it very disagreeable for travel. If less crown is given, the provision for wear is too small, and the drainage may not prove satisfactory after a comparatively short time.

For several months rains are apt to soften the top crust and cut up the smooth surface, but if patience is exercised and the road

machine is used to maintain the cross-section properly, it will be found that the puddling action of the traffic when the road softens is a great aid to final consolidation.

Construction with Artificial Mixtures.—From analyses made of materials proposed for use on account of accessibility, and from a study of their sand analyses, the proper ratio in which two or more materials should be mixed can be determined so as to secure the best possible results with the available materials. Three cases arise in which artificial mixtures are to be used:

(1) Sand foundation, where clay is to be hauled and proper mixture made by disk plowing and puddling.
(2) Clay foundation, where sand is to be hauled and mixture made as above.
(3) Soil foundation, where both sand and clay are to be hauled and mixture made.

In any of these three cases the proper mixture of the materials and the puddling action of traffic are necessary to secure a good consolidation. It takes considerable labor to secure a satisfactory mixture, but, except for this, there is no essential difference in the fundamental principles applying to construction with either artificial or natural sand-clay mixtures. The use of the road machine to maintain the cross-section and the height of the crown should be the same for each type of construction. For the softer varieties of sand-clay, the split-log and other forms of light drags may be used effectively in maintenance.

REPORT ON A SERIES OF TESTS ON CONCRETE COLUMNS REINFORCED WITH A SPIRAL OF STEEL.

By C. G. Wrentmore, M. Am. Soc. C. E., and Messrs. Hugh Brodie,* and C. O. Carey.*

To be Presented March 18th, 1914.

General Statement.

In 1907-08 the writers were designing some structures in which certain columns were required to carry heavy loads and would be subjected to considerable shock. The nature of the structures was such that columns of reinforced concrete offered certain advantages, sufficient in importance to warrant the use of that material, even though low stresses and consequently an excessive quantity of material might be required to insure safety. At about this time a number of failures of reinforced columns in important structures at various places in the United States were reported in the engineering journals, sounding a warning against a too liberal estimate of their strength, and plainly indicating the need of a careful study of such members from the experimental standpoint as a basis for safe design. Some experiments then made on the ultimate strength of columns with longitudinal steel

* Messrs. Brodie and Carey are Instructors in the University of Michigan.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

bars embedded in the concrete indicated that such reinforcement, unless hooped or banded at frequent intervals, could not be relied on to increase the strength of the column, and in some cases might even render its strength less. These experiments, however, were few in number, and the time available did not permit of their being carried out with sufficient care to render the results thoroughly trustworthy; but they served to turn attention to the hooped column, which had been discussed by Considère in his treatise, regarding which experimental information was very meager.

A series of tests on small columns was planned and partly carried out during the first half of 1908, but the departure of Mr. Wrentmore for the Philippines, in July of that year, interrupted the work, and since that time it has been continued by Messrs. Brodie and Carey at irregular intervals, at such times as their University duties would permit.

In all, 115 columns have been made, and usable results have been obtained from 104 of these; the remaining 11 were broken in storage or in handling, were found faulty in construction, or showed such erratic results under tests as to warrant their being thrown out of the list. Those which will be discussed here are Nos. 10 to 22, and 36 to 115, both inclusive, except Nos. 40, 55, 83, 86, 88, 91, 103, 108, 109, and 112, a total of 83 columns. The other 21, making up the 104, include the columns reinforced with longitudinal rods previously referred to, and some special cases which are not germane to the present discussion. The series is still incomplete, some of the sub-groups showing no tests, or only one or two, and others showing wide variations and requiring more tests to determine a dependable average. Moreover, the extensometer tests on a large percentage of the columns were only carried to 700 or 800 lb., and, later, when a comparison of results was made, it was found that it would have been desirable to have carried all tests to at least 1 400 lb. per sq. in. Some columns gave usable results on only one part of the test, as on ultimate strength alone, or extensometer measurement alone; however, in view of the care which has been exercised in carrying out the work, it is believed that the results obtained are worth placing on record, and they are here presented in the hope that they may add in some measure to the sum total of useful information.

ACKNOWLEDGMENT.

The writers take pleasure in acknowledging the assistance received from the Dean of the Department of Engineering of the University of Michigan in granting the use of the University laboratories and equipment for carrying on these tests, to Gardner S. Williams, M. Am. Soc. C. E., for suggestions which were of assistance in securing accuracy and uniformity in the results, and to H. H. Atwell, Assoc. Am. Soc. C. E., and Messrs. J. Schmutz and L. H. Neilson, of the Faculty of Surveying, and Messrs. H. A. Shuptrine, E. Olmstead, L. R. Manville, and M. D. Bensley, students in Engineering, all of the University of Michigan, who gave their time and work to assist in carrying on the tests.

AIM OF THE TESTS.

The tests were planned to determine the longitudinal and lateral deformations of the columns under various loads, increasing from zero to something above the probable maximum working stress, with varying quantities of reinforcement and at different ages, also the ultimate strength and the load at the first visible sign of failure. From the deformation could be determined the change in unit length for various loads, the modulus of elasticity, and Poisson's ratio. Comparison of the results should show the influence of the reinforcement on these several quantities.

DESCRIPTION OF THE COLUMNS.

All columns were approximately 4 in. in diameter and 27 in. long, over all, cast in a galvanized-iron mould set on a wooden bottom. The mixture throughout was the same, 1:2:4 by loose volume. The cement was Peninsular brand, bought from a dealer from stock, in fair condition, and as ordinarily used in construction. It was sampled and tested as for construction work, passing satisfactorily the standard tests recommended by the Special Committee (of the American Society of Civil Engineers) on Uniform Tests of Cement. The sand was bank sand from a drift deposit at Ann Arbor, secured from a contractor who made a business of furnishing it to the building trades, and was of a grade acceptable for first-class work. The granulometric composition is shown by Table 2. The coarse aggregate was broken limestone from the quarries at Monroe, Mich., and was passed through a $\frac{3}{4}$-in. and retained on a $\frac{1}{4}$-in. screen.

The mixing was done by hand, and under the personal supervision of the writers. In order to fill well about the spirals, it was necessary to use a wet mixture; it was too wet to be tamped with a small rod, but not so wet as to cause the materials to separate in pouring.

The reinforcement in Columns 10 to 14 was furnished by a commercial firm, built up and ready to be placed in the forms. The spiral was of high-carbon steel, $\frac{1}{8}$ in. in diameter, spaced as shown in Table 3. The spacing members were four $\frac{1}{8}$ by $\frac{1}{16}$-in. steel bars. No tests were made to determine the physical constants of this reinforcing material. These columns were tested only for ultimate strength and first sign of failure, and, for purposes of comparison, are included with similar columns tested at other laboratories.

The reinforcement in Columns 15 to 22 was wound on the concrete shaft, after casting, by placing the column in a lathe and winding the wire on under constant tension—sufficient to bed it slightly in the concrete. This was done just before testing, at the age of 28 days. The end of the wire was anchored securely to the column very near one end, the tension was applied, and a dozen turns were wound on as close as they would lie in order to insure against failure at the end; the spiral was then spaced by using the lead screw until within 1 in. of the other end; then another dozen turns were run on close together. The wire was then brought under the anchor and fastened, the tension was released, and the wire cut free. On these columns the wire had a diameter of 0.079 in., an area of 0.0049 sq. in., and the tension, as given by a spring balance, was 62½ lb. on some columns and 125 lb. on others, corresponding to unit stresses of 12 750 and 25 500 lb. per sq. in.

In the remaining columns in which reinforcement was used the spirals were made up and set in place in the form, and the concrete was then poured. The longitudinal members of the reinforcement were barely heavy enough to hold the spiral in place; they were strips of No. 24 gauge galvanized iron, $\frac{7}{16}$ in. wide, with notches, $\frac{7}{32}$ in. deep, accurately spaced by machine; the consecutive turns of the spiral were dropped into these notches and fastened by pinching down the lugs formed in cutting the notches. Four such spacing strips were used for each coil, and, as they were so light, considerable care was necessary to insure the proper location of the reinforcement. On final test to destruction, however, all spirals were found to have been spaced and

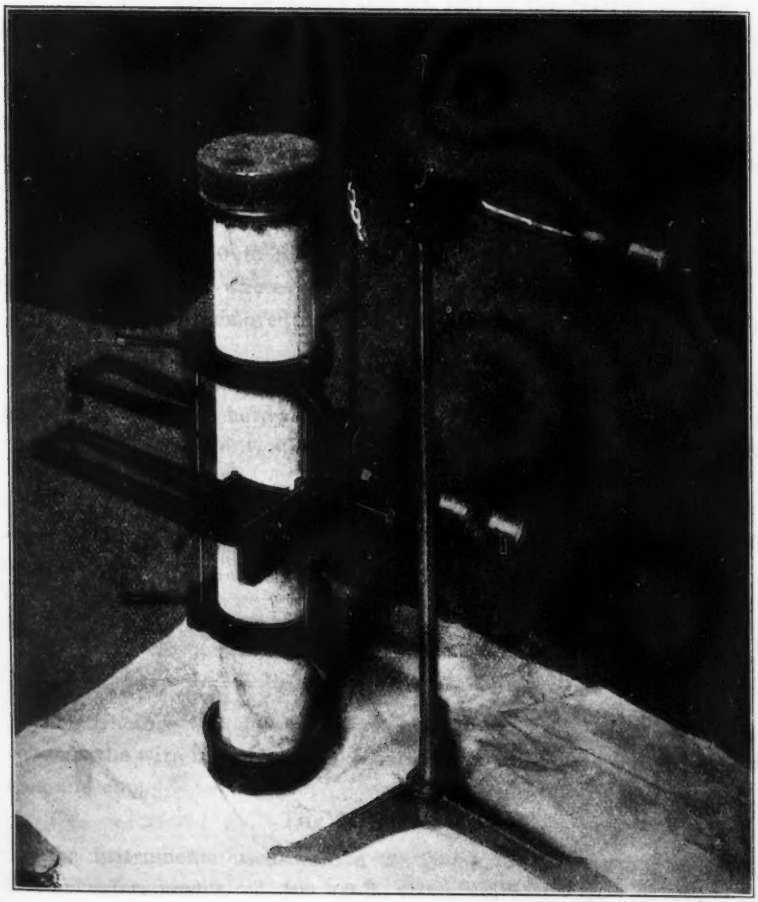

FIG. 1.—EXTENSOMETER.

centered accurately, although in some cases the longitudinal members had taken a spiral position, as may be seen on Fig. 3. A number of extra turns were given at each end of the coil, to make sure that failure should occur in the middle of the shaft, and a circular piece of ¼-in. mesh hardware cloth was placed in each end of the column to give it additional strength. In spite of these precautions, however, a number failed by splitting or crushing at the end, thus failing to develop the full strength of the shaft. The longitudinal spacing strips were not taken into account in estimating the percentage of reinforcement, as they were considered to be too slender to affect sensibly the column under test.

After being cast the columns stood for 24 hours in the forms, and then, except Nos. 10 to 22, were placed in water in the large naval experimental tank, where they remained until removed for testing. Nos. 10 to 22 were removed from the forms at 24 hours and cured in air in the laboratory.

The wire used in the spirals was of unannealed, copper-washed, soft steel, bought from a hardware dealer from stock. Under test it showed an average yield point, ultimate strength, and reduction of area as given in Table 1.

TABLE 1.

Diameter, in inches.	Ultimate strength.	Yield point.	Reduction of area. Percentage.	No. of tests.
0.105	92 330	85 780	50	35
0.079	95 260	87 870	50	45
0.062	78 000	70 000	80	45

The fracture was deeply cupped in all cases, and on crushing the columns the wire invariably broke with the same appearance of reduced area and cup.

The Instruments.

The instruments used were a 200 000-lb. Riehlé testing machine and an extensometer. A 100 000-lb. Olsen machine was available, but the larger clearance, the greater freedom from vibration, and the fact that it was not so frequently in use made the larger machine more desirable. The column was placed in the machine on a cushion of sand in a cast-iron cup which had a machined surface for bearing on the bed of the testing machine.

The extensometer, Fig. 1, was designed by the writers and built in the Instrument maker's shop of the University. The small variation to be measured rendered necessary extreme care and accuracy in construction, and especially the elimination of all lost motion. Knife-edges were ground straight in a Universal grinding machine after tempering, and the V-notches for the knife-edge bearings were made in two parts and similarly ground to true lines. The five rollers of tempered steel were ground to true cylinders, and as nearly of the same size as practicable, and afterward Nos. 2, 3, 4, and 5 were calibrated against No. 1 in a specially designed device.

The small amount of lost motion is shown by the fact that when the column was loaded and the scale-beam rose and fell between its stops a distance of about $\frac{3}{4}$ in. at the free end, the lateral mirrors traveled to and fro on the scale, showing clearly the increase and decrease of diameter of the column due to the small variation of load produced by this motion of the scale-beam.

The construction of the instrument is shown by Figs. 1 and 2. For longitudinal measurement, there are two cast-iron rings, *q*, connected by three telescoping rods, each made up of the rods, *r* and *s*, and the tube, *t*. The rings, *q*, are fastened to the column by setting up the screws, *w*, to a firm bearing. The rods, *r* and *s*, are then set in their seats in the rings and the nuts lightly screwed down on the spherical heads, as shown in the small sectional view. The tube, *t*, is slipped on and firmly clamped to the short rod, *r*, the longer rod, *s*, being left free to slide within *t* as the column shortens under load. The bar, *u*, attached to *t*, holds the roller between its face and the bar, *s*, being held to a steady pressure by the adjustable spring, *v*. The average of the readings of the three rods gives the deformation of the column.

For lateral measurement, the frame, *a*, with its arms attached, is hung by a chain from the counterbalance arm shown in Fig. 1, by the hook at *g*, which is fast to the sliding bar, *e*, which is moved by *h*. The bar, *e*, and the counterweight on *d* are adjusted until the bar, *a*, hangs level, and the weight on the counterbalance arm is adjusted until it exactly balances the weight of the instrument. It is then adjusted to the column in place in the testing machine, with the knife-edges, *o*, and the screws, *b*, bearing against the small blocks of plate glass cemented to the column. The pieces, *j* and *k*, are bolted rigidly to *a* when in use. The arm, *m*, is held to a firm bearing on its

knife-edges, n and o, by a spring and plunger in p. The distance between these knife-edges is 1 in. and the length from n to the end of m, on which the roller bears, is 10 in. The roller is placed between the end of m and the bar, l, the latter being held by a spring to a firm

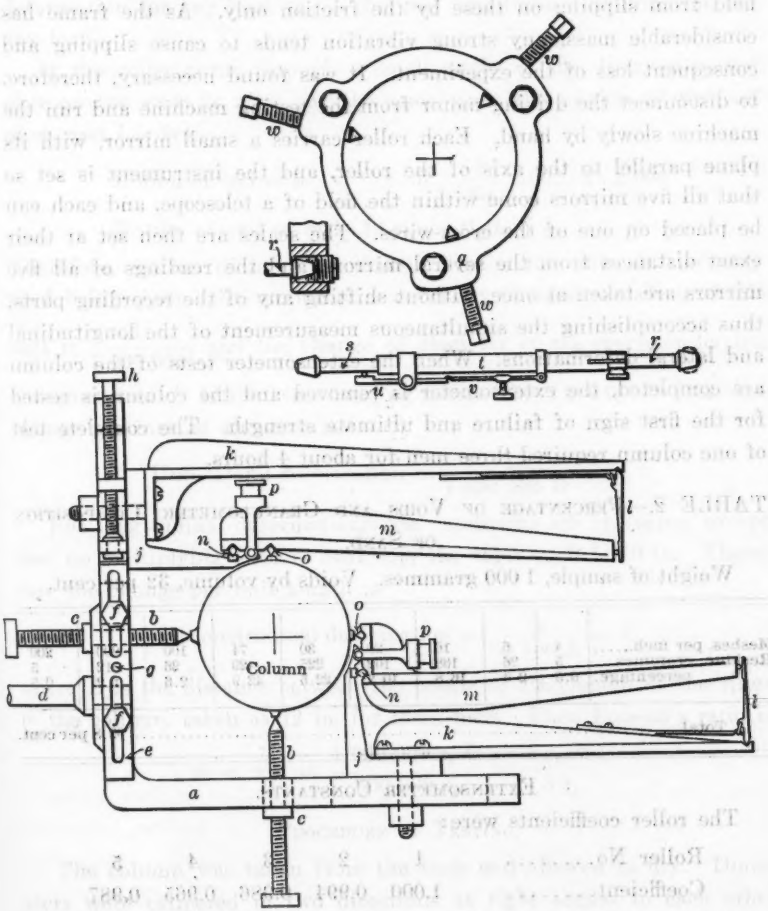

FIG. 2.

bearing against both its knife-edge seat on k and the roller. When all is adjusted, the screws, b, are made fast by the lock-nuts, o, so that all is rigidly connected to a except the arms, m, and the rollers. Any increase or decrease of diameter will cause m to rotate about n

and produce rotation of the roller. The average of the change shown on the two diameters is taken as the change in diameter of the column. The instrument when adjusted is free to move with the column, but none of its weight is carried by its bearing on the glass plates; it is held from slipping on these by the friction only. As the frame has considerable mass, any strong vibration tends to cause slipping and consequent loss of the experiment. It was found necessary, therefore, to disconnect the driving motor from the testing machine and run the machine slowly by hand. Each roller carries a small mirror, with its plane parallel to the axis of the roller, and the instrument is set so that all five mirrors come within the field of a telescope, and each can be placed on one of the cross-wires. The scales are then set at their exact distances from the several mirrors, and the readings of all five mirrors are taken at once, without shifting any of the recording parts, thus accomplishing the simultaneous measurement of the longitudinal and lateral deformations. When the extensometer tests of the column are completed, the extensometer is removed and the column is tested for the first sign of failure and ultimate strength. The complete test of one column required three men for about 4 hours.

Coefficient.....	1.000	0.994	0.986	0.965	0.987

Each reading from a roller is multiplied by its coefficient to give the corrected reading.

Referring to Fig. 2: From n to the end of m is 10 times the length n-o. The roller between m and l has a diameter, $2r = \frac{1}{10}$ in., approximately. R is the distance from the center of the roller to the scale.

taken as 100 in. for the transverse extensometer and 50 in. for the longitudinal one. s_1 is the distance traversed on the scale by the lateral mirror when a load is applied, corrected as above stated. s_2 is the same for the longitudinal mirror. λ_1 is the unit lateral deformation for any load. λ_2 is the unit longitudinal deformation for any load.

If the roller turns through a small angle, θ, the distance passed over on the scale is $2R\theta$. At the same time, the motion of the end of m past l is $2r\theta$.

$$\text{Motion of end of } m : s_1 :: r : R :: \frac{1}{20} : 100 :: 1 : 2\,000.$$

Motion of end of m is 10 times that of o.

Therefore, motion of $o : s_1 :: 1 : 20\,000$. Hence the unit on the scale used being $\frac{1}{50}$ in., the motion of o necessary to make a reading of this unit is $\frac{1}{1\,000\,000}$, and the change of diameter of the specimen having a diameter of D is the scale reading divided by 1 000 000. Thus the change per inch of diameter is:

$$\text{Unit lateral deformation} = \frac{s_1}{1\,000\,000\,D} = \lambda_1.$$

For longitudinal deformations, the conditions are the same, except that no multiplying lever is used, and the value of R is 50 in. Therefore the change per unit length is

$$\text{Unit longitudinal deformation} = \frac{s_2}{50\,000\,L} = \lambda_2,$$

where L is the distance between the points of attachment of the rings to the column, taken as 12 in. for these tests. Then Poisson's ratio is

$$m = \frac{\lambda_1}{\lambda_2} = \frac{1\,000\,000\,s_2\,D}{600\,000\,s_1} = \frac{5\,s_2\,D}{3\,s_1}.$$

Procedure in Testing.

The column was taken from the tank and allowed to dry. Diameters were calipered in two directions at right angles to each other at the bottom, center, and top. Two circles with planes normal to the axis were struck, 12 in. apart, to locate the attachment of the rings for the longitudinal measurement. A third was similarly struck for the position of the points for the lateral measurement. On this last circle, the extremities of two diameters at right angles to each

other being located, small blocks of plate glass were cemented to the column with faces made parallel by pressing them to their bed between two parallel steel faces. When these were firmly set, the rings were attached and the column was set with top down on the bed of sand in the cast-iron cup. Cotton waste was tamped lightly around the column to retain the sand. The column, with cap in place, was then set in the testing machine in an upright position, the bottom end on a bed of sand in a cup like that used at the top, and a light load applied to hold it in place, care being taken to secure a full even bearing on the sand. The transverse extensometer was set and adjusted as heretofore described.

The zero reading was taken with a total load of 100 lb. on the column, and thereafter increasing loads were applied and readings taken at each load, up to a maximum, then decreasing loads down to zero were read. On a few columns the loads were run up and back a second time, but usually only one run was made. These readings being completed, the extensometer was removed and the column was tested to destruction.

Behavior Under Test.

The driving gears of the testing machine caused considerable vibration when in action, and in some cases caused the lateral extensometer to slip on the glass plates. The readings showed plainly when this took place, and several tests were necessarily discarded on this account. By running the machine slowly by hand, this trouble was minimized, and usable results were obtained. Usually, the readings were fairly uniform and consistent, but, occasionally, erratic results were found, such as one mirror starting off with negative readings for a few loads, and gradually returning to positive ones as the loads were increased. There was commonly a noticeable difference in the readings between the two lateral, or among the three longitudinal, mirrors, showing that the column underwent lateral deflection. However, when the readings were averaged and plotted, the results usually were very fair curves.

In applying the increasing loads, the weight was set at the proper mark and the load was run up until the beam rose, the reading then being taken. The beam was never held up by the column, but always dropped showing progressive deformation.

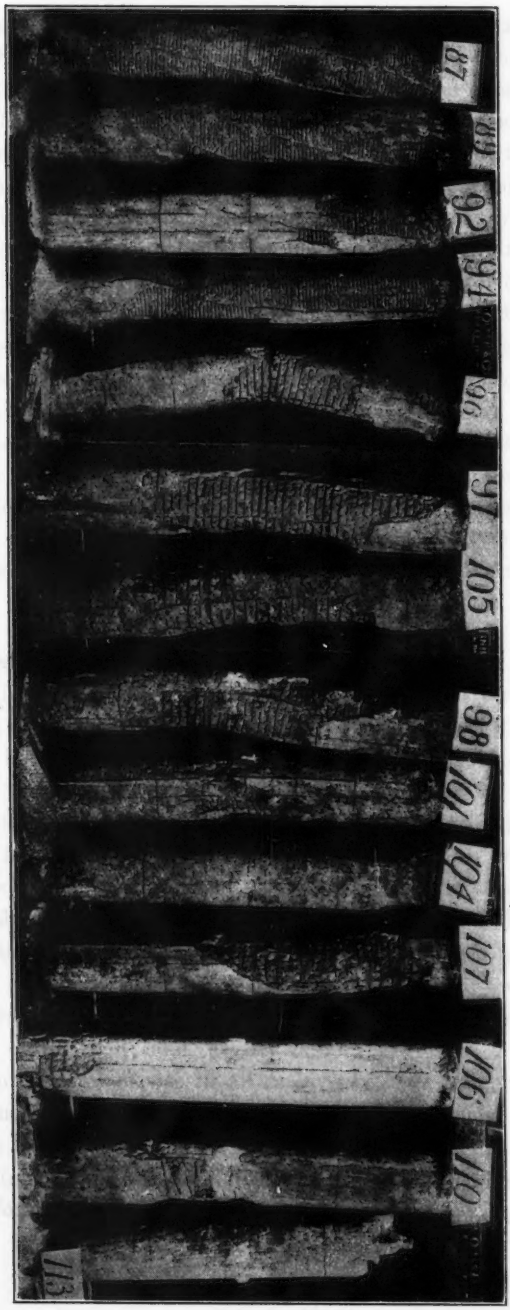

FIG. 3.—APPEARANCE OF CERTAIN TYPICAL COLUMNS AFTER TEST.

UNIV. OF ILL.

In loading to destruction, considerable lateral deflection usually appeared, the column frequently approximating the characteristic curve of the slender column with fixed ends. Extreme care was taken to observe the first sign of failure, which was shown by a flaking of the surface cement, commonly near the center of length of the column. In the columns without reinforcement, failure was abrupt, only two or three giving any previous indication, and that at a very small percentage below the ultimate load. In those with spiral reinforcement, it was always gradual, giving ample warning and time for observation. The outer concrete separated from the core in considerable sections and fell away, leaving the spiral exposed; with increasing loads, deflection appeared, the concrete of the core began to force out the hooping, and finally the latter broke, the concrete flying out at the point of the break as though blown out by a small charge of explosive; the wire showed a clean tension break. In a few cases the column failed at or near the end, showing imperfect construction. These cases were discarded unless the values were fairly high, as the local failure prevented the column from developing its full strength.

Computation of Values.

The area of cross-section was computed for all plain columns as a circle having a diameter equal to the mean of the six measured, two each at top, center, and bottom. The unit load for values of s_1, s_2, e, and m, for both plain and reinforced columns, are based on the area thus found.

For reinforced columns, the ultimate unit strength and the unit load at the first sign of failure are based on the area of core enclosed by the spiral. The percentage of steel is based on the volume of steel and the volume of core. The percentage shown in Column 14 of Table 3 is the ratio of total load at first sign of failure to total ultimate load. The average lateral deformation is the average of the distances traversed by the lateral extensometer mirrors on the scale, in fiftieths of an inch; and, as the column diameter on which this measurement was taken was in all cases very near 4 in., this reading gives the increase in lateral dimension of the unit cube in units of $\frac{1}{4\,000\,000}$ in. Similarly, the longitudinal deformation is the average of the readings of the three longitudinal mirrors, and gives the longitudinal deformation of the unit cube in units of $\frac{1}{600\,000}$ in. The

value of Poisson's ratio would be approximately $\frac{4\,000\,000\,s_2}{600\,000\,s_1}$, or $\frac{20\,s_2}{3\,s_1}$, but, in computing this, the exact diameter was used instead of the approximation of 4 in., so that the coefficient varies slightly from $\frac{20}{3}$.

The value of $e = \frac{E \text{ of steel}}{E \text{ of concrete}}$, and is used because it is quite as readily computed and plotted as the E of concrete, and, for purposes of this discussion, is somewhat more useful. It is computed as follows:

E of steel is taken as 29 000 000;

f_c = stress on concrete, in pounds per square inch;

$$E_c = \frac{600\,000\,f_c}{s_2};$$

$$\frac{E_s}{E_c} = \frac{29\,000\,000\,s_2}{600\,000\,f_c} = \frac{145\,s_2}{3\,f_c}.$$

The 10-in. slide-rule was used wherever time could be saved thereby, except for values which could be taken directly from tables.

Figs. 4 to 9, inclusive, show typical curves of s_2, e, and m, plotted to uniform scale, for columns Nos. 38, 46, 51, 58, 61, and 63. The unit for the s_2 curves is $\frac{1}{600\,000}$ in., that for e and m is unity. The curves for any column in the series may be plotted from the data for s_2, e_1, and m, in Tables 5, 6, and 7. The curves on Figs. 4 to 9, however, show the effect of unloading the column, as well as loading, but the tables do not.

Comparison of Ultimate Strength.

The effect of the reinforcement on the ultimate strength is shown by the comparisons in Table 4. The columns are grouped as follows:

Group 1.	Reinforcement	0.00 per cent.
2.	"	0.44 to 0.54 per cent.
3.	"	0.67 to 0.86 "
4.	"	1.16 to 1.35 "
5.	"	1.41 to 1.69 "
6.	"	2.02 to 2.32 "
7.	"	4.10 per cent. (One column only.)

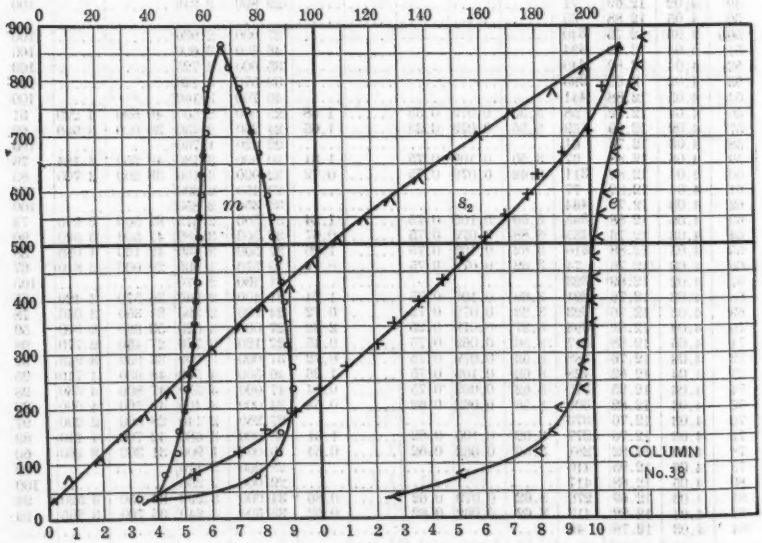

FIG. 4.

Plotting the average ultimate strength of each group, as shown on Fig. 10, gives four points for Group 1 and two for each of the others, except Group 7, which falls entirely off the diagram. The curve of Group 1 shows a consistent increase of strength with age, approximating in form to that of the age-strength curve of neat cement in tension, though the early increase is relatively less. For Groups 2 to 6 the ultimate strength is shown in full lines and the first sign of failure in broken lines.

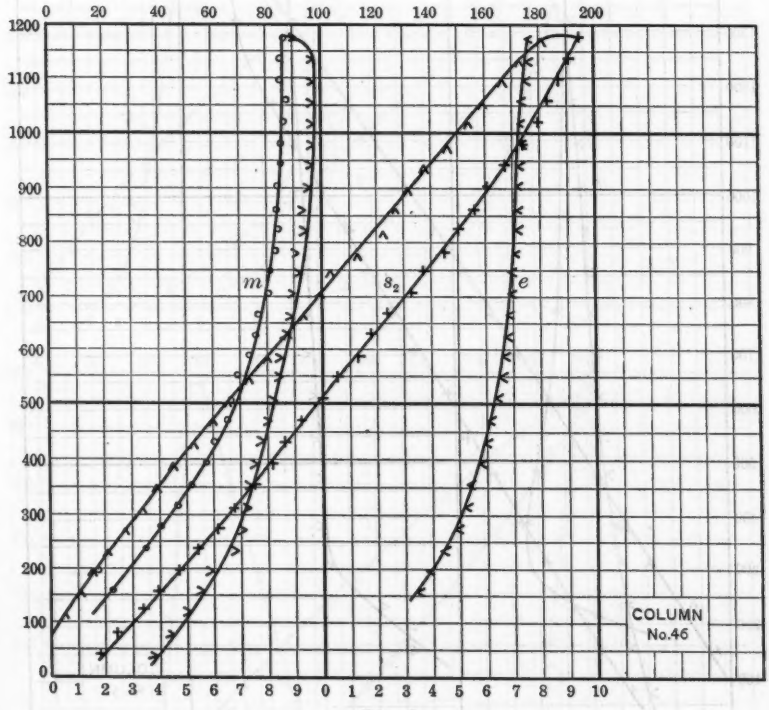

FIG. 5.

There are some irregularities in the relations of these lines, which are probably due to accidental causes, except the reversal of position of 2 and 3, which will be discussed later. However, all groups show an increase of strength with age, and generally with increasing quantities of reinforcement. The load for first sign of failure shows considerable irregularity in the long-time tests in Groups 5 and 6, but, as each of

these sub-groups contains results of one column only, such irregularity is plainly accidental.

Although the relation of the first sign of failure to ultimate strength is brought out more clearly by another diagram, this plotting is given to show the relations within the individual groups. The lack of har-

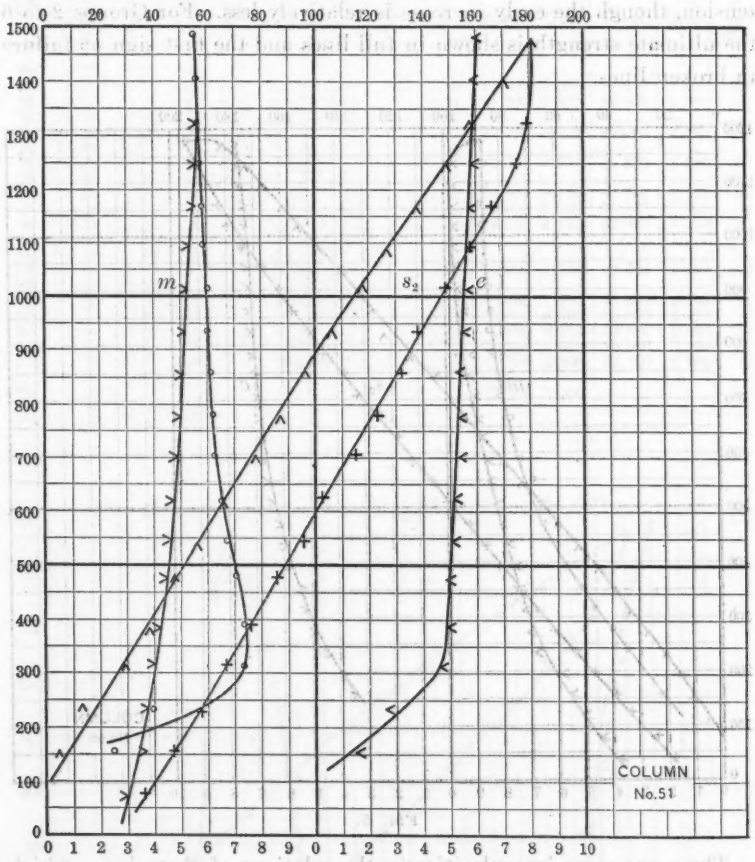

FIG. 6.

mony as the number of tests decreases, and the danger of generalizing from a few tests, are here clearly indicated.

The percentages of Column 14 of Table 3 are plotted on Fig. 11, using percentages of steel as abscissas and the values of Column 14 as ordinates. Here the short-time points, with the exception of that for

FIG. 8.

Group 3, lie close to a straight line through (0.100), and the long-time points lie on a curve at higher values. These lines show that, with from 0.80 to 1.60% of reinforcement, the columns at an age of 45 days, may be expected to give warning of approaching failure at about 80% of the ultimate strength, and, at an age of 1 year, this warning is given at about 90% of the ultimate strength.

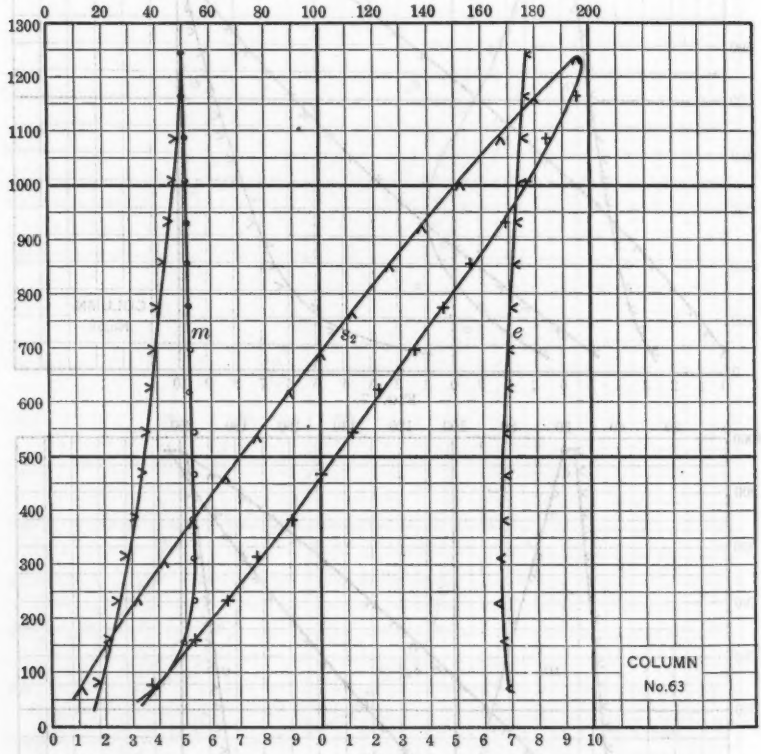

FIG. 9.

On Fig. 12 are plotted stresses at first sign of failure as ordinates with percentages of steel as abscissas, *M-N* being the curve for short-time and *O-P* that for long-time tests. For purposes of design, the values given by these curves would correspond roughly to the yield point of a steel member, in that, once determined with a reasonable degree of accuracy, this, rather than the ultimate strength, would control the allowable limit of working stress.

Although the small number of points leaves much to be desired, the general form of the curves seems to point to two conclusions: first, that the effect of hooping, in raising the first sign of failure, decreases with increasing age; and second, that even small quantities of steel exert an appreciable influence on this limit.

Plotting the group averages, with percentages of steel as abscissas and ultimate strength as ordinates, gives the curves of Fig. 13, *C-G-H* being the curve for an average age of 45 days, and *E-G'-K* that for approximately 1 year. These curves come nearly together at *G-G'*, and from that point lie close to the line, *A-B*, drawn from the origin through the point, *G*, the latter having the co-ordinates of approximately (0.0158, 4 000). Here the small number of tests in Groups 5 and 6, each three columns for short-time and one only for long-time, renders the portion, *G-H*, and especially, *G'-K*, questionable. In the absence of more complete data, assuming the curves as shown to be correct, within a reasonable limit of error, these curves show that, for percentages of steel greater than 0.0158, the ultimate strength of the column is not dependent in any measure on the age or strength of the concrete, but solely on the strength of the steel and the coefficient of friction of the aggregate, though with smaller quantities of steel the strength of the concrete is a factor, increasing in relative importance as the proportion of steel decreases. In other words, it appears that, with less than 0.0158 steel, when the cohesion of the concrete

disappears, the steel does not suffice to carry the load by its lateral hold on the granular, non-coherent mass, but that with the failure of cohesion of the concrete occurs the failure of the column; and, with a larger quantity of steel than this, the failure of cohesion in the

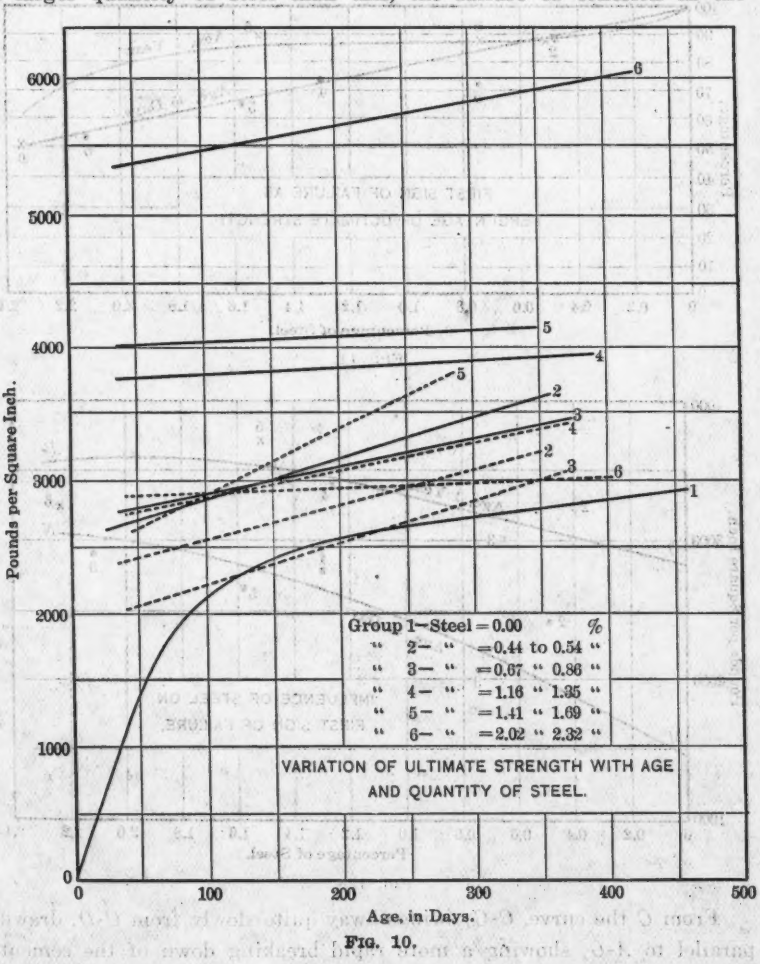

FIG. 10.

concrete does not produce failure of the column, as the steel acting on the core suffices to support the load.

Attention is here directed to the fact that this limit of 0.0158 is based on the volume ratio of steel to concrete, on wire having a yield

point and ultimate strength as shown in the table, and on a broken-stone concrete. With a weaker steel, or with aggregate material having a different coefficient of friction, this limit would be changed.

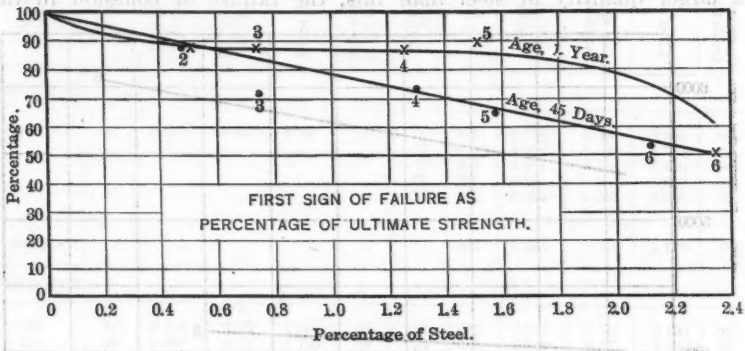

FIG. 11.

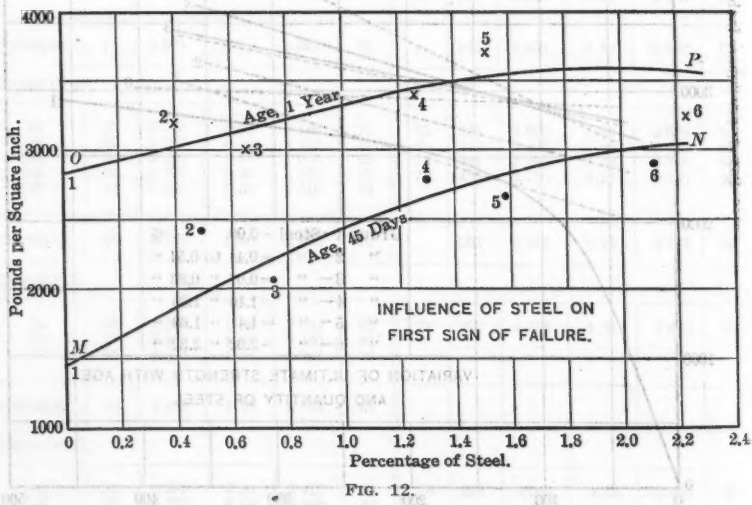

FIG. 12.

From *C* the curve, *C-G*, swings away quite slowly from *C-D*, drawn parallel to *A-G*, showing a more rapid breaking down of the cement bond as the load increases; though *E-G* draws away from the similar parallel, *E-F*, much more rapidly. Both, however, indicate clearly that the reinforcement is effective in raising the ultimate strength, even with small proportions of steel.

The ordinate to the curve at any point consists of two portions: that below *A-B*, due to the wire confining the granular mass, and that above *A-B*, due to the cohesion of the concrete; or, perhaps better, that below *A-B*, due to the reinforcing steel, and that above due to the cement bond.

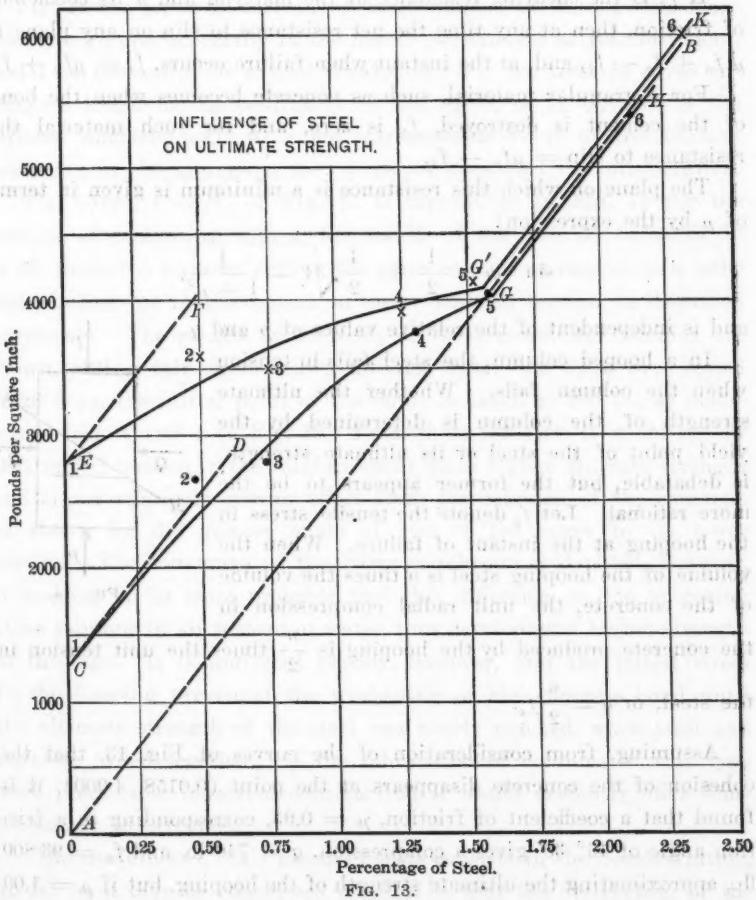

FIG. 13.

By rational methods the following is found, assuming that the column fails by shear on an oblique plane: Given a particle acted on by the forces, P and Q, at right angles to each other, producing stresses p and q on their normal planes (p being greater than q),

the resultant normal and tangential stresses on a plane, M-N, making an angle, ϕ, with the direction of Q will be

$$f_n = p \cos.^2 \phi + q \sin.^2 \phi$$
$$f_t = (p - q) \cos. \phi \sin. \phi$$

If f_z *is* the shearing resistance of the material and μ its coefficient of friction, then at any time the net resistance to slip on any plane is $\mu f_n + f_z - f_t$, and, at the instant when failure occurs, $f_t = \mu f_n + f_z$.

For a granular material, such as concrete becomes when the bond of the cement is destroyed, f_z is zero, and for such material the resistance to slip $= \mu f_n - f_t$.

The plane on which this resistance is a minimum is given in terms of μ by the expression:

$$\sin.^2 \phi = \frac{1}{2} \pm \frac{1}{2}\sqrt{1 - \frac{1}{1 + \mu^2}},$$

and is independent of the relative values of p and q.

In a hooped column, the steel fails in tension when the column fails. Whether the ultimate strength of the column is determined by the yield point of the steel or its ultimate strength, is debatable, but the former appears to be the more rational. Let f_s denote the tensile stress in the hooping at the instant of failure. When the volume of the hooping steel is n times the volume of the concrete, the unit radial compression in the concrete produced by the hooping is $\frac{n}{2}$ times the unit tension in the steel, or $q = \frac{n}{2} f_s$.

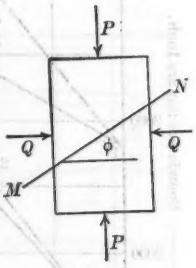

FIG. 14.

Assuming, from consideration of the curves of Fig. 13, that the cohesion of the concrete disappears at the point (0.0158, 4 000), it is found that a coefficient of friction, $\mu = 0.95$, corresponding to a friction angle of 43° 30′ gives a compression, $q = 740$ lb. and $f_s = 93\,800$ lb., approximating the ultimate strength of the hooping, but if $\mu = 1.00$ and the friction angle is 45°, $q = 680$ lb. and $f_s = 86\,000$ lb., or about the yield point of the spiral. It would seem, therefore, that, with a steel having a relatively high yield point, the question whether ultimate strength or yield point determines the strength of the column

is not an important one, because so small a variation in the angle of friction corresponds to so large a range of stress in the steel.

This method of treatment takes no account of flexure in the column, and, therefore, is applicable only to short columns.

The writers do not consider that the tests prove that the curves of Fig. 13 are typically correct. A large number of tests, giving more complete groups, especially in the higher percentages of reinforcement, would be necessary for a final conclusion; but the tests as given indicate a break in the continuity of the curve, as at *G*, and, as the rational analysis leads to a not unreasonable value of the friction coefficient in the aggregate, the curves are presented for consideration.

The curve, *C-G-H*, of Fig. 13 is reproduced in Fig. 15 for the purpose of comparing with it the results of the tests on Columns 15 to 22, inclusive, built by setting the plain column on centers in a lathe and winding the reinforcement on under constant tension, as described previously. The results of the tests of these individual columns are shown, with a fair curve drawn through them. As these were tested at 28 days, the initial point of the curve is taken at 900 lb., as determined from Curve 1 on Fig. 10. From these few tests it would appear that initial tension in the reinforcement gives higher ultimate strength and also a relatively greater effect from the cohesion of the concrete, as shown by the greater angle of rise of the curve in its lower portion. The soundness of the latter conclusion is doubted, however, it seeming to be more probable that this difference is due to curing these columns in air instead of water, thus developing a higher strength at this age. It is indicated plainly, however, that the initial stress in the hooping prevented the weakening of the concrete bond until the ultimate strength of the steel was nearly reached, when steel and concrete failed together. If the fabrication of columns of this type were practicable in actual construction it would evidently offer some advantage in strength.

The usefulness of this group of tests consists in the demonstration, so far as it may be considered conclusive, that the destruction of the bond of the concrete itself is restrained by the hooping, so that this destruction becomes a gradual process, instead of the abrupt one which occurs in the plain column, and that this restraining effect is produced, even with small percentages of steel.

On Fig. 15 are plotted also the points for Columns 10 to 14, inclusive, marked z; also from tests* by A. N. Talbot, M. Am. Soc. C. E., Columns 171, 172, 173, 181, 182, 183, reinforced with high-carbon steel, and marked T, and Columns 176, 177, 178, 186, 187, reinforced

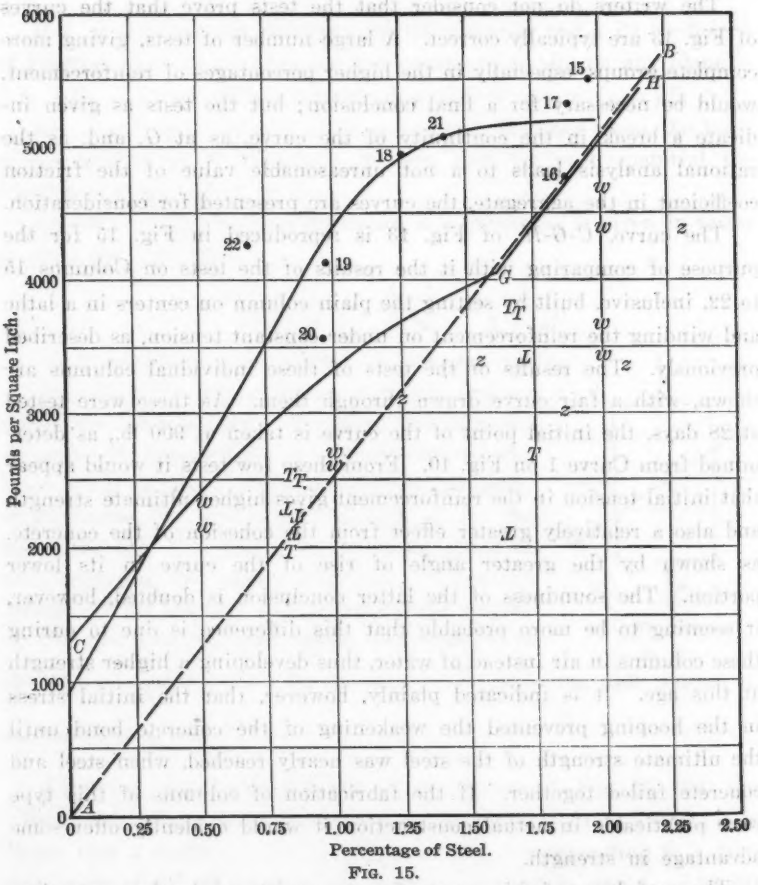

FIG. 15.

with mild steel and marked L; also from tests† by Professor M. O. Withey, Columns $C1$, $C2$, $C3$, $C4$, $H1$, $H2$, $L1$, $L2$, marked w. All the columns of this group are reinforced with hooping prepared by commercial firms, and differ only in minor details. Compared with

* Bulletin No. 20, Illinois Experiment Station.
† Bulletin No. 466, University of Wisconsin.

Columns 15 to 115 of this series, they differ first in having longitudinal or spacing members relatively much heavier, and second in the use of a heavier hooping wire spaced on a higher pitch.

The fact, noted by Considère, that a low-pitch spiral is more effective than one of high pitch is brought out clearly here. These points lie in a fairly close group, but all are well below the curve, *C-G-H*.

There is no reason to believe that these lower values are due to inferior concrete, nor, on account of their consistent grouping, can it be argued that they are due to differences in conditions of the tests, unless, because of the fact that these were cured in air and the *C-G-H* columns were cured in water. A consideration of Fig. 10, however, shows the line of Group 2, with 0.44 to 0.54% of steel, lying above that of Group 3, with 0.67 to 0.86 per cent. It happens that all the columns of Group 2 were reinforced with the 0.061 wire, and that Groups 3, 4, and 5, have each only one column with this fine wire, all other reinforcement being heavier. The writers, therefore, believe that the points under discussion lie below *C-G-H*, because of the fact that the spiral is of coarser wire and consequently higher pitch.

Values of s_2.—The stress-strain curves show a permanent deformation which is greater in the short-time tests. This is shown by arranging in two groups, the first including all columns from 84 to 115, all of which were loaded under the extensometer to 700 lb. per sq. in., and all at approximately the same age. These show on the 100-lb. line a length of 53 units (of $\frac{1}{6000}$ in.) between the ascending and descending curves. The second group includes Columns 46, 48, 51, 52, 53, 54, 60, 62, 64, 67, 69, 71, 73, 74, 75, 79, 80, 81, and 82, all but four of which were loaded to 1 400 lb., and all above 1 150 lb. have an average age of 352 days and show on the 100-lb. line a length of 35 units.

In the majority of cases these curves show a satisfactory uniformity, but some exceptions appear, as Column 72, tested at 388 days, which shows an abnormal lack of resilience, the load dropping from 1 400 to 1 000 lb. before recovery began.

For examining these results to determine the influence of the hooping on them, the columns are grouped in Table 5 in the same manner as for ultimate strength. The strains here are read off from the plotted curves, instead of being taken from the tables.

The average values of these strains, using ages in days as ordinates and strains as abscissas, are plotted on the diagram, Fig. 16, where

the numerals show the group numbers. Separate curves are shown for stresses of 400 to 900 lb. per sq. in. Here appears the unexpected condition that the plain columns show less strain than those which are reinforced. Before beginning the tests the writers had expected that, at least in the higher stresses, the columns would show, both in the s_2 and the m, just the opposite. If the strain in the reinforced columns had been less than in the plain ones, or if no difference between the two had appeared, the explanation would be simple; but, that the presence of a spiral of steel should be accompanied by a greater deformation

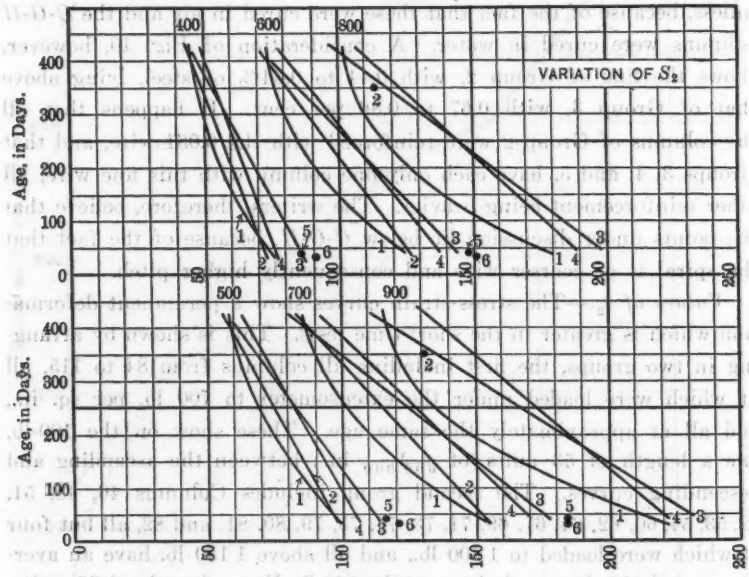

FIG. 16.

does not find a ready reason, unless it be that accidental peculiarities have existed which have escaped observation, but which, nevertheless, were sufficient to produce the condition shown. The consistency with which this runs through all groups leads to the opinion that the same results would be found by a repetition of the tests. That the shrinkage of the concrete, causing initial compression in the steel, might be the cause is untenable, first, because the concrete was immersed in water during the entire aging period, and the shrinkage, therefore, would not occur so as to produce this result; and second, because if the steel spiral were under initial compression one would expect to find

m, at short time, less for reinforced than for plain columns, whereas the curves for m show precisely the opposite. The only explanation which the writers can suggest is that the presence of the reinforcement, with its rather closely spaced wires, may have prevented in a measure the thorough elimination of bubbles and small voids, thus rendering the concrete as a whole less dense. Moreover, Professor Talbot, has discussed* the same condition, which he found to exist in his experiments, and on which he places the same interpretation.

These curves indicate that, within the limits of ordinary working stresses, spiral reinforcement does not noticeably lend assistance to the concrete in carrying the load, but that, if such assistance is developed, it is at stresses well above the ordinary working limits.

Values of e.—The values of e have been computed and plotted for the ascending curves only. In Table 6 the columns are grouped as before, and the values are as read from the plotted curves.

The average values from Table 6 are plotted on Fig. 17, the ages, in days, being the ordinates and the values of e the abscissas. The curves show a close agreement for both plain and reinforced columns at 425 days, and separate more widely with decreasing age and increasing stress. As these are derived directly from s_2, they show the same general relations between the plain and reinforced columns, and the comments made regarding the stress-strain curves apply with equal force here. The evidence of these curves is decidedly against the use of values of e greater than 10 for computing the strength of reinforced columns. It runs above that value only for the combinations of short time with high stresses, a combination to be avoided in practice as much as possible.

Values of m.—m is the ratio of longitudinal to lateral deformation, the two being opposite in kind when the member is stressed in one direction only, and its value, m, in terms of the observed quantities, becomes

$$m = \frac{\lambda_2}{\lambda_1} = \frac{5\ D\ s_2}{3\ s_1}.$$

This involves one more observed quantity, s_1, which is more difficult to measure, not only because it is very small, but also because of the likelihood of the instrument slipping. The curves show less

uniformity than those of s_2 and e, and a few have been thrown out of the general averages where they appeared to differ widely and erratically from the others of the group. In Table 7 the columns are grouped as before.

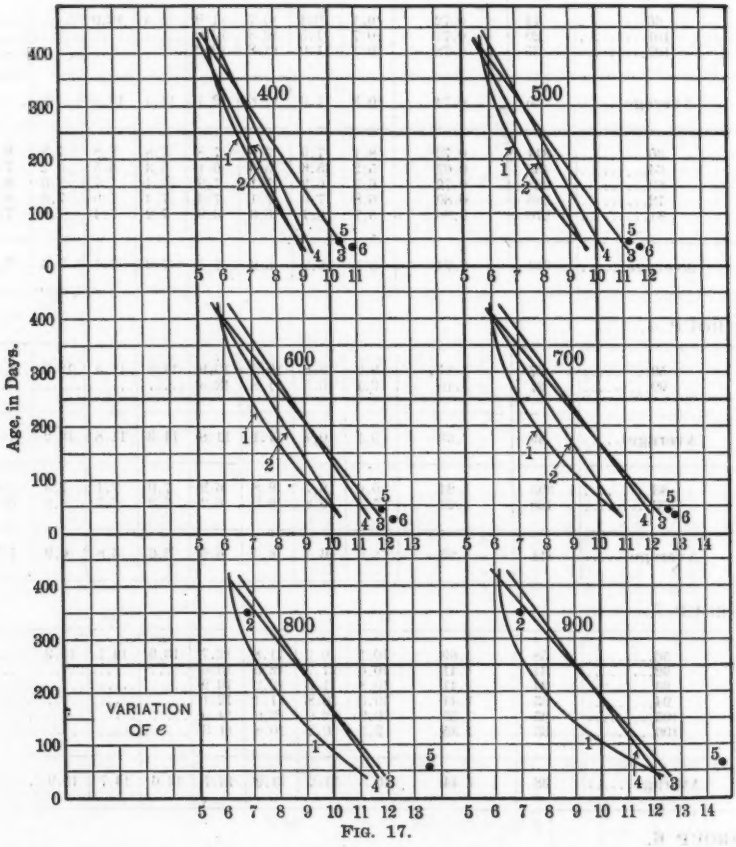

FIG. 17.

The average values from Table 7 are plotted on Fig. 18; with ages, in days, as ordinates, and values of m as abscissas. The single column of Group 2, tested at short time, gives values which for the lower stresses appear to be too high, but the other points lie fairly close together, the value 7 for long time and 8 for short time representing fair averages. On the 800 and 900-lb. curves the value for long time drops below 7. In the few cases where this constant has been used in

discussions, as noted by the writers, it has been assumed as equal to 4, the value derived by Grashof under certain assumptions made by Saint Venant. Estimates based on this would evidently be considerably in error. The value, 7-8, as here found is not surprising when compared with the value for steel, which is about 4.

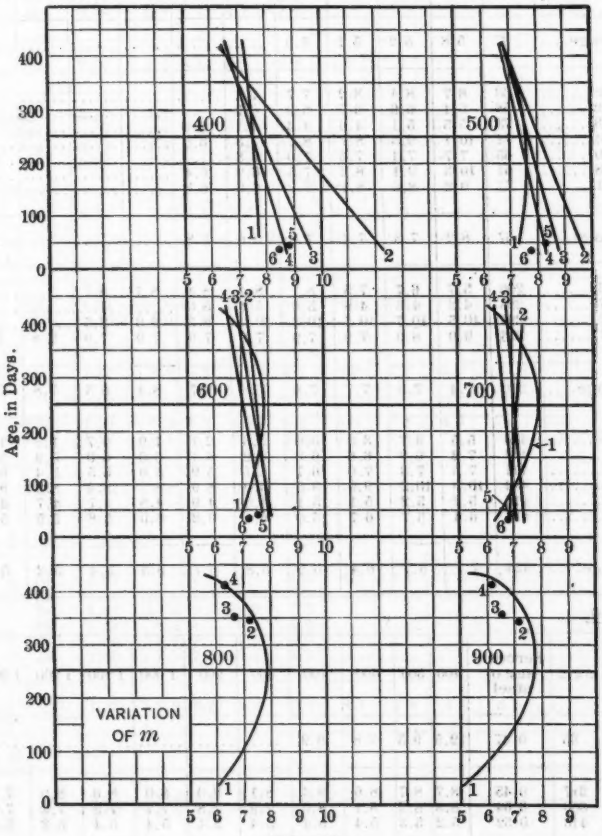

FIG. 18.

As compared with steel, concrete is lacking in density, has numerous small voids, and is granular in nature, with possibly a state of tension existing in the interstitial masses of cement due to the shrinkage of the latter in setting, under certain conditions. The first effect of applying a compressive stress to it would probably be to decrease

the volume by linear deformation in the direction of the stress, with little or no lateral enlargement. If this should actually take place, one would expect the value of m to be infinite at the beginning of application of load, and to decrease as the load increased, giving a

curve such as is found in Columns 52 or 62. Generally, however, the curve runs from a lower value up to a maximum at a stress which roughly averages 275 lb. per sq. in., but which may be anywhere between 100 and 500 lb., or may not be clearly defined at all. The

points up to the 500-lb. stress are irregular in location, and it is often impracticable to lay a fair curve through them, indicating that the material is settling together somewhat irregularly and adjusting itself under the imposed load, not uniformly, as would a homogeneous mass, but somewhat spasmodically, until a stage is reached where the mass is thoroughly compacted, and all the initial stresses are relieved; from this point the deformation becomes quite consistent, as is shown by the values of m becoming quite regular, the points varying but slightly from a fair curve.

This same tendency to irregularity is shown slightly in the s_2 curve, but far more plainly in the e curve, where the points are irregularly placed, frequently showing a considerable break in continuity at some point. This irregularity of e seems to be without any law, except that it disappears at stresses of from 200 to 400 lb. There is no reason to suppose that slipping of the extensometer would be more likely to occur here than at higher stresses, and the fact that the values of e, which depend only on the s_2 readings, show an irregularity similar to that of m would indicate that this is not due to slip in the instrument.

It is the conclusion of the writers, therefore, that below about 400 lb. per sq. in., the concrete deforms under the load quite irregularly and without any law; that at about 400 lb. the causes of this irregularity are largely eliminated, and that thereafter the action conforms closely to a definite law which can be represented by a fair curve until some higher limit is reached; which limit lies well beyond ordinary working stresses, and is not defined by these tests. At this limit the destruction of the cement bond would begin, and the curves would become irregular again.

Conclusions.

From the foregoing results the writers deduce the following conclusions, as applicable to the materials used in these tests:

(1) The value of Poisson's ratio is approximately 8 for short-time and 7 for long-time tests.

(2) The value of e is in general below 10, only exceeding that value for short time and high stress.

(3) Spiral reinforcement does not, by its restraining effect on the core, perceptibly affect the values of m or e for stresses below 900 lb. per sq. in.

(4) Spiral reinforcement does not perceptibly assist the concrete in carrying the load within the limits of ordinary working stresses.

(5) The limit at which the first visible sign of failure occurs is raised by spiral reinforcement. This effect is greatest in short-time tests, and is perceptible for all percentages of reinforcement.

(6) The plain column fails abruptly, giving no warning of approaching collapse. The hooped column may be depended on to give warning of approaching failure at from 70 to 90% of the ultimate strength, when not less than 0.50% of steel is used.

(7) The deformation is quite irregular up to about 400 lb. per sq. in.; above this it is quite regular up to a limit which is not defined by these tests, but is well above allowable working stresses.

The tests indicate, but cannot be said to prove conclusively, that:

(8) The ultimate strength of the column is increased by spiral reinforcement by an amount roughly proportional to the quantity of steel used, up to the limit of 1.58%; and above this limit the ultimate strength is simply the amount which can be carried by the granular core supported by the spiral, but with no cohesion of its own.

DISCUSSION ON VALUATION FOR THE PURPOSE OF RATE-MAKING.*

By Messrs. Onward Bates, Jared How, W. H. Courtenay, V. K. Hendricks, E. W. James, W. W. K. Sparrow, William J. Wilgus, J. E. Gibson, H. C. Vensano, William W. Crehore, and C. P. Howard.

Onward Bates, Past-President, Am. Soc. C. E. (by letter).—The valuation of public utilities for the purpose of rate-making is one of the great economic questions of the present day in the United States, affecting as it does the value of investments aggregating thousands of millions of dollars, and the income from wages and dividends of some millions of people. The able report submitted by the eminent members of this Committee will carry great weight, and will doubtless be quoted back and forth by those who are engaged in the practical solution of the problems involved. This report, however, is admittedly incomplete, and is submitted with the reservation of the privilege to add to it. Consequently, it should not be taken as the last words of the authors. Mr. Bates.

The Government of the greatest nation in the world is committed to the policy of the regulation of big business, and incidentally of little business, and we have the example of men without business experience directing in detail how business shall be conducted, holding over the heads of citizens engaged in business the threat that the Government itself will take business out of the hands of its owners and conduct it as a Government monopoly. The notable present instance of this policy is the regulation of railway rates by the Interstate Commerce Commission, and it is in the minds of many people interested in rail-

* This is a discussion on the Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities, presented to the Annual Meeting, January 21st, 1914.

Mr. Bates.

ways that a continuation of this policy will ruin this line of business endeavor, in so far as the interests of the men, women, and children who are railway stockholders are concerned.

The future of all public utilities is dependent on the rates which the public, through its Governmental instrumentalities, may establish from time to time. "Justice" will be the watchword of those who name the values and of those whose property is valued. The Committee, under the heading "General Principles Involved in Valuation for Rate-Making," writes:

"The primary requirement in the valuation of a public service property is that justice shall be done both to the owner of the property and to the public." * * * "The exercise of the power to regulate rates should be based on equity to both parties.

"It has been well settled by the highest Courts that the owner of such property is entitled to a fair return upon a fair value of the property utilized in or reasonably necessary to the service."

Justice, however, is often obscured. It appears from the foregoing quotation that the highest Courts depend for justice on the fairness of the valuation. It is to be expected, and it is certain to happen, that controversies will arise between the owners of property and those who place values on such properties, and it is only natural and altogether probable that partisanship and bitterness will be engendered between the representatives of property interests and of the authority which undertakes to establish the value of property.

At this point we meet what the writer considers one of the worst features of Governmental ownership—two parties disputing over values, of which, one party, with the prestige of Governmental authority behind him, is clothed with the power to do injustice, while the other party is practically helpless. Justice, as has been stated, depends on the fairness of the party to the controversy which holds the power of decision, and equity can only be secured by having the valuer fair and just and competent.

We are all prone to evil. Men are not perfect, and when engaged in a fight are inclined, during the heat of action, to forget the principles of equity and justice while endeavoring to secure an advantage over an opponent. There is an additional danger to vested interests to be expected from the appointment of incompetent valuers. This is the day of professional reformers and efficiency enthusiasts, most of whom are not under the conservative and sobering influence of personal investments which are at stake. At a time when the Government is planning an organization for the purpose of valuing public utilities, which will require a great number of men, most of whom should be experts, and with the condition that such qualified experts are generally in the employment of the public utility corporations, it is to be expected that men with bright minds and plausible language will find in this organi-

Mr. Bates.

zation a market for their talents. These talents may be very great, but, if not balanced by experience and a sense of responsibility toward the interests at stake, may be dangerous instruments in the hands of the Government, leading to great injustice toward its citizens.

An illustration of what may happen in this line is to be found in the seventy-eight questions submitted by the Interstate Commerce Commission to the railways as a preliminary to the granting of an increase in rates. These questions are too long to be quoted here, but the necessity for an increase in rates seems to have been lost sight of by the Commission, which has started an investigation entirely aside from the business question to be determined, with the only possible result that it will create a delay in the administration of justice.

If it be assumed that, in the future, railway rates will be, or may be, based on the valuation of the physical property of railway corporations, we will find a large proportion of the membership of this Society engaged in this work of valuation, and divided between a staff of engineers employed by the Interstate Commerce Commission for this purpose, on the one side, and the engineers employed by the railway corporations, on the other side. Engineers are already being lined up in these two classes, between which there will be great diversity of opinion on many points, notably on the questions of depreciation and land values. Under these circumstances it will be most unfortunate for the report of the Committee to be considered as anything more than an expression of the opinions of its distinguished authors. The writer is willing to be corrected if he is wrong in making the statement that the Committee was not appointed to make a report on valuation for the purpose of rate-making. Its function was "to formulate principles and methods for the valuation of railroad property and other public utilities." The Committee may find justification in making a report on "valuation for the purpose of rate-making," in its statement that "Valuations of the property of public service corporations may be made for a variety of purposes," and its report on this particular variety may then be considered as only one section of a general report, the other sections of which are to be furnished later.

The Committee goes on to say:

"It is, of course, true that the principles and methods of valuation for rate-making are in most respects the same as those involved in the valuation for other purposes."

Granting this truth, if the Committee had confined itself to a general report, it would have avoided the criticism of engineers, specially interested in rate-making, who differ with the Committee in some of its conclusions. The Committee's report is on "Valuation of Railroad Property and Other Public Utilities for the Purpose of Rate-Making." The immediate and most important application of the principle of valuation for the purpose of rate-making is found in the case of the

Mr. Bates.

railways; but the report seems to be based largely on experience with water-works and public utilities other than railways. The report would have been more acceptable if its treatment were limited to local utilities which constitute monopolies in their own limited territory, such as water-works, gas plants, electric properties, etc. As a matter of fact, the report is based on the condition of, and legal decisions relating to, such utilities; but it also covers in a desultory way questions of valuation of railway property, and really lumps the whole proposition to include them. It attempts to apply the same principles to circumstances and conditions which are entirely unlike.

The rates to be charged for gas, water, telephone service, local transportation, etc., in Chicago, are not governed or influenced by the rates permitted in St. Louis or Milwaukee. The same principles may or should govern; but there are no competitive influences or conditions. For the regulation of those local utilities which are non-competitive, or competitive only in a very limited way, principles of valuation may be formulated which will be approximately fair and just; but the situation with railways is entirely different. Whatever advantages may come from railway valuation, the proper fixing of rates is not one of them.

The Government valuation of railways is not declared to be for purposes of rate-making. Authority to make the valuation, after repeated requests by it, was granted to the Interstate Commerce Commission which wanted it for whatever value of any kind there might be in the information. The Commission has repeatedly declared that rates cannot be based on valuation, although it may be one of many elements to be considered under certain conditions. It would be just as fair to assume that the valuation is being made for the purpose of Government purchase and ownership, as to assume that it is for the impracticable purpose of determining fair rates.

The impossibility of basing railway rates on the plan of fair interest return, or even profit, on the value of the property, is so patent that it ought not to require any re-statement. The whole railway system is competitive, and the Government, just now, is bent on breaking it up into still smaller competitive units. Between certain terminal points there are half a dozen or more lines with different values, whatever principle of valuation is used in determining them. All must charge the same rate; and no road can, of itself, fix its own rates.

The existing rate structure is the product of commercial, competitive forces, and as a whole is found, even by regulating bodies, to be about right. It needs constant adjustment to meet changing conditions and to insure reasonable equality. Following a world-wide change in wages and all costs, the entire rate structure may need to be increased horizontally—as is the case at the present time—but no road or system, even if legally permitted, could raise a rate by itself,

Mr. Bates.

because its traffic would immediately desert it and go to other lines. This is not true of local public utilities, because there is practically no other available supply of service for the public.

If all the railways were in one system and ownership, rates might possibly be predicated on value of investment, and changing costs be met by changing rates, so as to insure an average net earning. The strong lines would then support the weak; but, with diversified ownership and the demands of all parts of the country for adequate transportation facilities, nothing of the kind can be done, and speculation regarding it is useless and misleading.

The Committee should either have differentiated clearly and omitted railways from its discussion, or should have omitted entirely that part of its report relating to "purpose of rate-making."

The questions involved in the valuation of public utilities for the purpose of rate-making are of such importance and of such direct interest to the members of the Society that the fullest discussion of them should be encouraged, and final conclusions should not be adopted until discussions are exhausted. With constant changes occurring, the time when discussions will be completed may never arrive, and final conclusions may be indefinitely postponed. Such a result ought not to be regretted. We must act according to our best present information, and continually move on to better conditions.

It should not be assumed that the questions to be solved in valuing public utilities for rate-making are wholly of an engineering nature. In fact, the engineer has only a limited function in their solution. The valuation of public utilities for the purpose of rate-making calls not only for engineering knowledge, but as well for the knowledge possessed by lawyers, by financiers, by real estate experts, by business men, and by accountants, all of whom should state the cases, from their points of view, before an attempt is made to formulate definite conclusions.

The work of valuing railway property, recently inaugurated by the Interstate Commerce Commission, will be done under certain disadvantages, some of which are:

A large organization, not trained to the work at hand, but gathered at one time from such material as is available, with the certainty that the railways will retain in their own service the experts who are fitted by experience for this work; the demand for results from this organization necessitating conclusions before this new occupation is capable of producing correct conclusions based on knowledge. In other words, results will be published before the business is learned, and conclusions will be to a greater or less extent untrustworthy.

There will be the interpolation of politics, directly and indirectly, into a fight, for power on one side and for existence on the other side.

Mr. Bates.

It is claimed by railway officials that the total value of railway property in the United States is $15 000 000 000, more or less. It is not true, as might be inferred from the assertions of politicians and of sensational newspapers, that this property is owned by a few magnates whose only concern is to rob the public. The railways, collectively, are a useful and valuable asset of the whole nation. They are owned by the holders of their stocks and bonds, mostly innocent investors, including men and women who have bought the securities with the accumulation of their savings, and children and helpless people are represented by the investment of trust funds in these securities.

The American Society of Civil Engineers cannot afford to place its endorsement on a report which may be used to increase or decrease the returns to the owners of these railway properties. If the report was absolutely conclusive, the Society could with propriety stamp it with approval, establishing the truth, without regard to its effect on any interest; but this is not the case. The principles claimed and the conclusions drawn will be disputed by a large number of the members of the Society. The Committee itself does not consider this report as final, for, in foot-notes at the beginning of the report and on page 74 it reserves the right to add to the report before its final publication.

This report should be received by the Society without any endorsement, good or bad. It is carefully prepared, and contains much valuable information. It will be interesting and useful when published in the *Transactions*, but it should not be assumed to be an expression of the Society as a body. It should simply be received with thanks. The reception and publication of such a report is an honor to its writers. The Society is careful to publish the statement in its *Transactions* that it "is not responsible for any statement made or opinion expressed in its publications." This statement, which applies to every paper published by the Society, should have equal application to the report under consideration, and should apply with special effect to it, for the reason that there will be great diversity of opinion regarding its contents. Even if it were considered necessary for the Society to take action regarding the approval of the report, it would not be right for such action to be taken at the Annual Meeting, which is attended by a comparatively small number of members. If a division is sought on the question of approving the report, it should be submitted to the whole voting membership of the Society for such action.

The writer has received a letter from Mr. Jared How, an attorney-at-law in San Francisco, criticizing the Committee's treatment of the subject of depreciation, and, being in full accord with Mr. How's criticisms, he offers (with the consent of Mr. How obtained by telegraph) this to the Society for its information, and as a contribution by Mr. How to the discussion.

JARED HOW, ESQ.* (by letter).—The writer's attention has been called to an advance copy of the report of the Special Committee of the American Society of Civil Engineers appointed to "formulate principles and methods for the valuation of railroad property and other public utilities" which is designed apparently to be presented to the Annual Meeting of the Society. The writer has been allowed only a casual inspection of the report, and was advised, of course, that what he learned from it was to be held in confidence. Nevertheless he feels at liberty to mention it and criticize it. Mr. How.

The writer paid no attention to the contents of the report excepting so far as it deals with the subject of depreciation. He had too little time to read the subject matter of that topic with care; but is impressed with the idea that the Committee takes an unfortunate attitude toward it.

The basal principle of the relation between a public utility, a steam railroad, for example, and the public, is that of contract. The right to construct and operate a railroad is not a general right which appertains to every citizen as such. It is a right obtained only through the grant of a franchise from the sovereign power. The grant and acceptance of the franchise create a contract, the consideration of which on the part of the public is executed by the grant, and on the part of the grantee is executory and rests in the obligation to exercise the franchise in the manner contemplated by the grant. So a railroad company, having accepted a grant of a right to construct and operate a railway as a common carrier, is under contractual obligation to operate it as such and to furnish adequate and safe facilities for the conduct of all business which shall come to it. In other words, it is under obligation to keep its road and equipment up to 100% condition for efficiency, and to operate it up to that standard so far as the needs of the public require service. The manifest difference between the relation with the public of a warehouseman or an innkeeper, for example, and the owner of a railway, is that while the use of the property of each is of such character that the public has an interest in it and therefore may regulate the exercise of the use for its own protection, the warehouseman and innkeeper are under no obligation to continue their properties in the public use, and the owner of the railway is under such obligation. Furthermore, the warehouseman and innkeeper are not under obligation to furnish ample accommodations to serve all who shall apply to them. Each of them is justified in refusing to accept offered patronage, on the ground that he lacks facilities to care for it. The owner of the railroad property is not thus justified. If his facilities are insufficient, he must provide himself with more. The only pos-

* Attorney-at-Law, San Francisco, Cal.

Mr. How. sible ground for the distinction is that the warehouseman and innkeeper have no contract relation with the public, and the owner of the railroad has such a relation; and his obligation growing out of that relation is to provide himself with such property and to operate it, when acquired, in such manner as shall be, not only inoppressive to the public, but, as well, adequate for the reasonable necessities of the public for the contemplated service for which his franchise was granted to him by the sovereign.

The fact that property of a railroad company is devoted to the public use does not make it public property. It is still private property, although it must be used for the service of the public; and, as such private property, it is under the protection of the provision of the Constitution of the United States that no State shall deprive any person of property without due process of law—and by "property" is meant, of course, the profitable use of property, as well as the title to it and dominion over it. Whether an owner of property is deprived of its profitable use seems to the writer to be clearly a question of fact to be determined by the application of the principles of economics, and not a question of law. The writer, therefore, comes to the consideration of the question of depreciation of railroad properties—the precise question being whether confinement of a railroad owner, whose property is maintained in 100% condition of efficiency, to a return on its depreciated value predicated on its cost newly produced, and not on its efficiency as an instrument, is, economically considered, a partial deprivation of the valuable use of his property.

The writer has before him, professionally, an estimate, made by an engineer of a State, of the present value of a line of railway. This railway was constructed as one task within a period of about 2 years, and cost about $5 000 000. The property was operated for some special traffic during construction. The valuation was made as of a date about 20 months after the road was turned over to the operating department. The State engineer finds its original cost and its reproduction cost; and then he estimates the "condition per cent." of each item of physical property, and averages them for the total, with the result that he estimates the present value—the value on which the owner is entitled to a return without interference by the State—as 95% of the amount of present cost of the property. If the property actually and reasonably cost $5 000 000, 2 years before this valuation was made, and could reasonably be reproduced at the time of the valuation for not less than that amount, as might well be assumed, then, if the owner shall be limited at the time of the valuation to a return on only $4 750 000, it seems to be clear enough that somewhere he has wholly lost, or has at least lost the valuable use of, $250 000. There is no force in the suggestion that he is entitled

to earn and lay aside this $250 000 during this period of 2 years in which the depreciation is alleged to have accrued. Even if he shall be able to earn it, he may not consider it as a return of a part of his investment and devote it to his private use as such. He is under exact obligation to use it in replacing the depreciating articles when they shall have depreciated to the point of ineffectiveness. In other words, because the proper maintenance of the property is the very first charge against the earnings of a railroad company, and because the property must be maintained ordinarily in perpetuity, money properly necessary for replacement of portions of the property when they shall have depreciated into inefficiency, and reserved by the company for that purpose, may just as well be said to be devoted to the public use as may the physical property of the company actually used in operation. It may, perhaps, be invested by the company until the necessity for its use arises, but if the investment proves unfortunate and the money is lost, it must be replaced, and, apparently, at the expense of dividends which otherwise might be properly payable; and, if the depreciation fund is invested and produces income, of course that income ought to be included in the general income of the company on the net of which the reasonableness of its rate of return is to be figured. Therefore, if the physical property is to be valued on a depreciated basis, obviously the depreciation fund necessarily segregated for the purpose of covering depreciation should also be valued, and a fair return should be allowed on both. If one builds a line of railroad 150 miles long, the cross-ties may all be laid in one year and may cost $325 000. Assuming the life of the ties to be 8 years, the railroad, in the eighth year of its existence, is none the less valuable to the public and none the less valuable to the owner, if he has on hand, and applicable to no other purpose, money sufficient to replace the cross-ties at the end of the year. Why then should he be limited to a return on the value of the property, less cross-ties, unless, indeed, he shall have added to that lessened value the amount of money which he shall have laid aside as necessary for furnishing new cross-ties? The writer cannot avoid the conclusion that if the owner is thus limited he is deprived of the valuable use of a portion of his property devoted to the public service.

Mr. How.

This is not much of an argument. The writer has not time to be as convincing as he is sure the soundness of his views on the question would permit. He writes because he thinks it will be calamitous if the Society goes on record in favor of economic practice, which seems to be utterly iconoclastic, and without a dissent.

W. H. COURTENAY, M. AM. SOC. C. E. (by letter).—Under the head of "Engineering", occurs the following statement:

Mr. Courtenay.

Mr. Courtenay.

"On railroads it is commonly estimated that the engineering cost will amount to 5% of the physical valuation of the property, exclusive of overhead charges."

The Committee proceeds to give certain specific examples of the engineering cost of other public service work, but does not give any specific examples of railroad work other than the subways in Boston and the Pennsylvania Railroad tunnels, both of which are out of the ordinary.

If the Committee has other data as to the ratio of the cost of engineering to that of construction on railroads, it would be desirable information.

Mr. Hendricks.

V. K. HENDRICKS, M. AM. SOC. C. E. (by letter).—This report covers the question of valuation in an excellent manner, getting down to the fundamental principles, and the writer considers the method proposed good for appraising property with a view of obtaining an equitable sale price. However, it requires a change in the system of accounting now in use on railroads, and as the same results can be obtained for rate-making purposes by using the valuation new, without changing the accounting system, it seems preferable to omit depreciation for rate-making purposes. It would be quite objectionable to change the system of accounting on all railroads.

In addition to this objection, it is believed that the use of the valuation new would cause less danger of errors through determination of the exact status of depreciation on each property, and would thus produce more uniform results, which would be more equitable to new and old properties alike.

By using the valuation new, it would be necessary, for the party calculating a rate determination, to consider each long-lived item separately, using the adopted percentage (which is practically uniform) corresponding to Columns 6 or 7 of the table showing the "Equal Annual Payment" method, and taking no account of the amount actually charged to operating expenses for the maintenance of such items. Short-lived items, which could not conveniently be given such special consideration, would be considered through the operating charges for maintaining such items, in the same manner as proposed by the Committee. By eliminating the actual depreciation for each individual property, the work of preparing the valuation, of all railroads, for instance, would be materially reduced and also the work of the "rate-maker", in that his calculations on long-lived items would be made from tables based on the expected life of the various items, and would be uniform for all similar properties, instead of requiring a different set of calculations for each year of any one property's life. This method accepts the theory contained in the Committee's report, and merely provides for a different method of application.

Mr. Hendricks.

The writer, therefore, recommends that, for rate-making purposes, the Society endorse the use of the valuation without any allowance for depreciation. This is an arbitrary ruling, but attention is called to the fact that in its report the Committee has made an arbitrary ruling in distinguishing between the method of handling long-lived items (tentatively assumed as having a life of 5 years or longer) and short-lived items, such as lining and surfacing of track, etc., the maintenance of which is just as much a restoration after depreciation as is the maintenance of the long-lived items.

Under the heading, "Application of Equal Annual Payment Method", it is stated that "the placing of additional ballast on a railway roadbed" should be charged to current expenses. The writer thinks this should read "the replacing of ballast on a railway roadbed", as new and additional ballast should certainly be charged against the capital account.

Mr. James.

E. W. JAMES, ASSOC. M. AM. SOC. C. E. (by letter).—In the large mass of expository and argumentative material produced during the last three years on the matter of valuation for rate-making purposes, only a small percentage can be dignified as contributions to the literature of the subject. The most prevalent fact—so common, indeed, as to be usual—is the failure of writers on the subject to establish any fundamental principles; and next, to confuse, sometimes in unexplainably simple ways, the elemental economic truths. The early days of many public service corporations display a tangle of promotion, corruption, lease, combination, purchase, and reorganization. Original records in many cases are lost. As a result, the discussion of physical valuation has been largely confined to consideration of the ultimate, technical details of some practicable method, to the neglect of important underlying principles. Valuation has been usually argued from the point of view of the material interests of the disputants. It has been only within the past two or three years that really serious conclusions have been arrived at. The report of the Committee, as presented, gives something lucid, fundamental, and unbiased, on which to hang discussion. The Committee deserves much credit for covering the subject in such detail, and at the same time in recognizing the basis in principle so essential to the whole matter. The report is a most valuable contribution.

At the same time, it was to be hoped that somewhat fuller exposition would profitably be made with regard to the economic and social principles that most certainly form the substructure of the whole valuation edifice. The Committee recognizes this idea when it states that:

"The primary requirement in the valuation of a public service property is that justice shall be done both to the owner of the property and to the public."

Mr. James.

This implies "fair rates" adjusted to produce "fair returns"; but it is obviously necessary to go back of this statement. It would not be just to close our eyes to past conditions, in any of their aspects, and rest our justice on present contingencies alone. Some papers have discussed at length the violation to property rights that would inevitably flow from any valuation that did not produce a fair return on the money investment of the present holders of stock. Such a valuation, of course, would do magnificent justice to the present stockholder; but, unfortunately, it would be saddling the public with a burden of fictitious values of all kinds for an indefinite future. This extreme case shows that the actual investment of the present stockholder is dangerously subject to sharp contraction in value; that such investments, heretofore seemingly sound, are to be a source of loss; that the investing public, like the proletariat buyer and more modest wage-earner, cannot look to the public for guaranty of all their past transactions. The investors took chances, naturally in the hope of adequate gains. It would be highly unreasonable, now, to remove all or nearly all the element of risk from such investments and assure to the stockholder for all the future a fair return on all the paper values he holds. The fact must be frankly recognized that someone is going to lose, and perhaps lose a great deal, in any adjustment of conditions flowing from rate-regulation on a valuation basis. It is inevitable that an older ground of justice than present conditions afford be sought and accepted as the really equitable and effective one.

In support of this, consider for a moment the recent events in connection with the passing of a dividend by the New York, New Haven and Hartford Railroad, and the insolvency of the St. Louis and San Francisco. As a result, perhaps, of the intricate financial maneuvering indulged in by the managers of these roads, the stockholders have had to accept some investments that are likely to turn out bad. They are going to lose some money, perhaps lose only paper values. Maybe they have been mulcted by trusted officials. In any case, however, whatever degree of truth there may be in any of these suppositions, certainly the general public should not be called on to relieve the stockholder of loss, or guarantee him for the future a fair return on funds out of which, frankly speaking, he has been cheated. So, it must be accepted that present justice cannot be done. Present holders cannot be entirely protected. It would be as just to have a public guaranty that all past real estate ventures by individuals in a given community shall result in gain, or at least in no loss. What the community should do in the future in this matter, however, is quite another affair.

This point of view probably makes the injustice loom large; but is the degree of probable injustice as great as it appears? Considering the holdings of stock in such roads as the Louisville and Nashville,

Mr. James.

the Pennsylvania, and the New York, New Haven and Hartford, it is probable that not more than a very small percentage of all public utility stocks that may be affected with loss as a result of rate-regulation on a fair plan, are held as *bona fide* investments by the people who, for instance, deposit in savings banks. A large mass of these holdings are held by direct, though in some cases now temporally remote, virtue of past manipulations. The holders took large risks and knew it. Their holdings do not represent vested interests of a sort that the public is bound for all time to hold sacred. In the past these holders have made huge gains; often their predecessors made huge gains. The profits they hoped for when they assumed their original risks have been forthcoming. Now, it appears likely that there will be a period of change, a time of reaction, perhaps some loss; but, in essence, the injustice will be of a blameless sort. In some cases innocent investors will lose, some homes will be impoverished, some lives saddened; but such painful facts are a part of all economic change, for good or bad, and are everywhere recognized in the common-sense fact that all investments cannot be successful. "Lambs" have been losing for years on the stock exchanges of New York, Chicago, San Francisco, and New Orleans. "Suckers" have invested millions of hard-earned, lonely dollars in wild-cat schemes of all kinds that appeared to them to be just as certain of returning substantial profits as the Pennsylvania or the New York, New Haven and Hartford Railroads. It is pitiable, but it is true.

A deeper-founded justice must be sought whereon to base an arrangement for fixing rates. It would, the writer ventures to suggest, have been profitable and illuminating had the Committee included in its report a more extended examination of the principles that are sure to be recognized sooner or later. Especially does this aspect of the general question appear inviting in connection with the most wise suggestion of the Committee, that:

"It would be entirely just and equitable, and it is highly desirable to provide by law that future public service properties should be valued on the basis of their actual reasonable existing investment."

The great value of this suggestion cannot be too soon recognized and acted on. No problems of any complexity would exist regarding such valuations, for the method of appraisal would be stated in advance. The experience that German municipalities have commonly had indicates that American concerns are quite ready and able to enter the field of furnishing public utilities when the investment is closely scrutinized by State or municipal authorities, when the rates are fixed, and when all net receipts above a certain permissible income on actual, reasonable investment are returnable to the State or city.*

* "Municipal Government in Continental Europe," Albert Shaw, pp. 52, 350, *et seq.*

Mr. James.

These conditions are considered satisfactory, and are met by American investors abroad; it is reasonably assumable that they would be acceptable to American investors at home. The sooner the conditions and limitations affecting future public utility valuations are prescribed, the better temper and security will be enjoyed by that part of the business world involved.

This recommendation of the Committee regarding the provision for making valuations of new utility properties, or for revising old valuations henceforth, indicates that, however much the Committee may believe in cost-of-reproduction-new as the most satisfactory method for making present-day valuations of old properties, it, nevertheless, is of opinion that actual reasonable cost to date of the property useful and usable in the public service would be the most just and satisfactory basis for valuation purposes. If the Committee recommends it for the future, it must at least accept its principle as sound; and therefore failure to use it for the valuation of old properties flows from considerations of expediency or compromise.

In spite of the fact that the Committee has chosen not to emphasize the fundamental principles, or to explain at greater length its opinions in this regard, it nevertheless arrives at generally sound conclusions relative to many of the matters which have long been in dispute.

There are, however, such fundamental principles, and although a general discussion of them belongs rather to the field of the economist, and may be considered by some as much too academic in nature to be of really practical value, still there is no denying that the closer we adhere to the course prescribed by sound and true principles, the more certain it is that substantial justice will be done to the greatest number. When justice is referred to as entering into the purposes or results of physical valuation for rate-making, an ethical principle is assumed and admitted, though perhaps unconsciously. This is an aspect of valuation that has not received the emphasis it deserves. A study of the economic and social phases of the subject may be made much more illuminating that it has been. It appears that such a study would provide a solvent for several of the problems now in dispute among writers of undoubted ability and experience. In the first place, the public attention has not been directed toward corporation control because it had nothing else to busy itself with. The movement toward physical valuation is not an erratic one. The public's point of view has of late years been changing. People are seeing that they have an interest in public service corporations different from that concerned merely with securing good gas, steady current, accommodating trolley service, or pure water. The new laws providing for physical valuation as a basis for determining rates for the use of public utility products or services are an evidence of this change of attitude.

That the public, the user, has been slow to recognize its real interest

Mr. James.

in public service corporations does not in the least lessen the rightfulness of that interest, or its substantial basis in fact. A savage has little or no ethical life; for, although an ethical principle may be absolute, *per se*, the strength of that principle applied depends on contributory circumstances of a nature to compel its recognition. Circumstances of corporation growth, the misuse of the power flowing from privileges granted to individuals by public official bodies, have at last forced the user of the public utilities to recognize his ethical right to consideration.

The interest of the user in the public service company is, of course, first of all, material. The company furnishes some service necessary to health or to the reasonable comforts of modern life, or something necessary to business. These services cannot generally be secured except from the public service corporation. For this reason the corporation is looked upon rightly enough as a quasi-public organization. It is no longer a private affair. In addition to this material interest, arising in the need of the community for fresh and pure water, light, heat, and transportation, there is the other, deeper consideration spoken of above. This flows from the material interest, and is best described as an ethical interest. It is not merely by equity or expediency that the user has rights in public service utilities. It is because he puts something into the business. What he puts in is, from the viewpoint of the user, fixed capital; he cannot withdraw it, and heretofore has had little or nothing to say regarding the management of it. Much of this fixed capital, supplied by the user of the public service utilities, is in the form of franchise privileges granted by the user, through his representatives in the local legislative body, for a period of years or in perpetuity. It is just as surely a vested interest as the money of the bond holder which has laid rails, strung wires, dug ditches, or erected pumping stations and gasometers. The fact that the consumer turns the management of his interest in the business over to the other party, together with the fact that when once these contributions are made they cannot practically be withdrawn, establishes the right of the user to fair treatment at the hands of the public utility company. Still stronger appears the user's right to fair treatment when it is considered that he is, in the very nature of the case, the residual investor. That is, under any plan to establish such rates as will provide a "fair return" to the money investor, the user must hold himself ready at any time to meet all demands for financial support involved in the operations of the utility. The user may not provide additional money capital in the early years of development, and may never indeed do so; but, if such becomes necessary, the user must, we admit, assume the burden of interest charges created by the required borrowing. Mutual obligations between the user and the producer follow naturally as a result of mutual interests.

Mr. James.

These obligations are as binding on one as on the other. Responsibility for fair treatment has in the past rested with the producer exclusively, because he has occupied the position of control. Unfortunately, the user has not been convinced, by the treatment that he has received, that his rights have had the recognition to which they are entitled.

A very interesting account of some of the increases in capitalization which have been made by railroads during the past 40 years, appeared recently.* Though the citations are doubtless extreme, their number is so large and the sums involved so enormous, that, had no other instances occurred, there is sufficient ground for the introduction of sudden and drastic control of the financial management of the railroads. At the same time, much praise is due to the operative management for their successful efforts to pay dividends on no less than $784 000 000 for which not a cent has been added to the value or earning capacity of the railroads. After extended consideration, Professor F. W. Taussig declares, "it is doubtful whether the whole mechanism of irregular and swollen capitalization was at any time necessary or wise."†

Nevertheless, it has been the user who has had to pay the bill, and, as a quasi-partner in the concern, it has obviously not been just to him to add paper capital which shall stand for all time and on which he must pay dividends.

As a result of these conditions, the present movement toward some degree of financial supervision has resulted. It is time that the relative obligations of both the users and the producers be understood. The railroads are by no means the only public service corporations involved, but they are by far the most important, both in relative value and in economic status. Further, they are to-day so generally the only corporations of a semi-public character whose life has been long enough to become seriously complex or whose records have been seriously impaired by neglect or loss, that a solution of the question of regulation as applied to railroads will, if satisfactory, serve as a solution of the more general cases.

The fact that the railroads hold so prominent a place among public service corporations, the added fact that among such corporations they stand almost alone in doing an interstate business, and consequently are the most prominent subjects for the exercise of control by the Interstate Commerce Commission, gives them a place in the discussion that cannot be deprecated. In accord with this condition, every development of practicable methods of valuation has held the railroad in chiefest consideration. It is doubtless due to conditions existing in the accounting offices of the railroads, that the general

* "The Plight of the Railroads," W. J. Lauck, *North American Review*, Jannary, 1914.
† "Principles of Economics," Vol. II, Chapter LXI.

opinion of those who have had to give consideration to these matters is strongly in favor of cost-of-reproduction-new as a basis of valuation for rate-making. Mr. James

As the writer has pointed out previously, the Committee recognizes the weight of opinion in favor of such a method, but at the same time supports the view that in the future the actual reasonable existing investment should alone be accepted as a basis of the same valuation. Apparently, the Committee has adopted cost-of-reproduction-new instead of original-cost-to-date merely as a matter of expediency, and in a spirit of compromise toward the confusion of conditions existing to-day among railroad records and old methods of accounting. In the writer's opinion, it would be much fairer and much nearer conditions of justice if the basis of valuation were made original-cost-to-date, just as nearly as it could be arrived at. In many cases this cost could be arrived at but remotely; nevertheless, it could be found in many cases as accurately as cost-of-reproduction-new. Nothing is gained in compromising on a point of principle. Rather, first, establish the principle. If it is advocated as good for all the future, it must be good enough for all the past. If the principle is established as applicable to the past, the law can then legalize it for the future. Indeed, the difficulties of uniformly applying a set of principles to conditions that the past hands down to our time are an argument for statutory action. In the presence of these difficulties it will be necessary to adjust methods of application. This can be done. It is much better to adjust the application in particular cases than to sacrifice a principle. If attention is given to that principle suggested above, that the user has, by virtue of existing conditions, an ethical right in the property of any public service corporation that acts under a franchise or to which government has transferred at any time the right of eminent domain, it will be seen that there is only one just basis of valuation. That is cost-to-date, actual, reasonable investment. The investment does not necessarily include all the money spent in creating the utility. It is no part of the user's duty to secure to the investor a return on funds spent unwisely, unnecessarily, or in any improper way.

Of course, those who support the position taken by the Committee cite the fact that complete records for cost-to-date do not exist in numerous cases. Such contention is doubtless true; but, admit this, adopt the cost-new method, and at once uncertain conditions are met, and details are prescribed that are really an effort to approximate cost-to-date. Assuming that the records are lost or imperfect, what is the essential difference between an appraisal made in an attempt to approximate original cost-to-date and one based on cost-of-reproduction-new in which "the original conditions should control," and in which costs "should be based upon physical conditions existing

Mr. James.

at the time the various portions of the property were built?"* The Committee recognizes again that the original cost is the one to be approximated, when, in its summary† it suggests that "average prices prevailing during a period of from five to ten years prior to the date of valuation should be used." In this way the present and the past are made to overlap, and just when this shall be done and to what extent is itself a nice question. For who shall say when the old becomes old, or how much of the new remains new? After all, is not the question but little more than one of definition? Does not the Committee resort to the method it considers less desirable in order to correct too faulty results produced by the method it considers best? Is not the valuation suggested by the Committee, under any name one pleases, after all, the actual reasonable investment represented by the properties under consideration, as nearly as it can be found? It appears to be, so it should be fairly met. In the ethical principle suggested above there is sufficient cause for adopting such a basis of valuation.

Furthermore, this ethical principle is a solvent of several problems that excellent authorities now disagree about. This disagreement, as so frequently is the case, arises in all probability because there is no common ground of principle on which to rest the discussion. If we recognize the ethical right of the user in the public service corporations, we have at once the principle we need. Consider for instance the matter of land valuation. The Committee, after writing off depreciation, sees that the appreciation presents a perplexing question, and states:

"The Courts have recognized that the corporation is entitled to earn from the public the sum necessary to offset the depreciation in the value of its structural property; similarly, the public is entitled to receive from the corporation due recognition of the increase in value of those portions of its property which appreciate in value."

Would the Committee hold that the public should receive any allowance due to a settled, stable grade, as contrasted with a new, green embankment? Consider this matter of land rather in the light of the ethical principle involved. The difference of opinion is really over the unearned increment. The usual and principal argument to support the inclusion of the unearned increment is that the public service corporation should not be denied what every land holder is allowed. Professor Taussig adopts this same position,‡ but points the way to an answer. Of course, if a valuation were being made for sale, taxation, or rental purposes, the inclusion of the increment would be right. If a utilities corporation chooses to rent or sell, it doubtless

*"Committee's Report," pp. 18, 15.

†"Committee's Report," Section 9, p. 71.

‡ *Supra.* Vol. II, Chapter LXI.

Mr. James.

is entitled to take advantage of the unearned increment, if it can find a purchaser on such terms; but the unearned increment of the land does not represent an investment of the producer but of the user. The increment arises from the development of the land contributory to the railroad. It is greatest in sections where the development is greatest. It is in essence a contribution of the community. The community is nothing more nor less than the user in an aggregated form, and as we have seen, the user is a co-investor with the producer in public utility properties. Obviously, no part of the return on the user's investment should be included in a "fair return" to the producer. It follows, of course, that lands donated, whether by a person, by a commercial body, or by government, should not appear in the valuation at all.*

The Committee itself may have had some misgiving with regard to the decision to include unearned increment. For the existence of a doubt is suggested in the expression used: "that if it be admitted that the [acquired] property is to share in the increase, etc."

The recognition of an underlying principle would not have led the Committee to decide that donations of either money or land by a community should be capitalized and made a basis of dividends to be paid by the community.

It is, of course, unnecessary to state that all legitimate expenses incurred in connection with the acquisition of land, all damage, transfer, and severance costs, should be included as a part of the cost of the land to the corporation.

Likewise, all necessary engineering charges, legal expenses, interest during construction, just exactly as during any later time, should all be allowed, and the recognition of an underlying ethical principle supports this view. Why, then, does the Committee say that "the amount of the overhead charges applicable to any property should be determined on the basis of the prices prevailing at or near the time of the valuation, but under conditions existing when the plant was created?" It will be as difficult to approximate the conditions existing twenty years ago as to approximate prices paid twenty years ago, and probably much more so. The aim should be to approximate both conditions and prices at the time of acquisition, and, indeed, the Committee probably sees this when it says, "the proper purpose of a cost of reproduction estimate of the value of real estate is to ascertain the cost of acquiring such real estate under the conditions existing at the time of its acquisition."

The Committee goes on to recite some special values attaching to land. Undoubtedly, if such values were recognized at the time of acquisition, and if a corporation was forced to pay a price for them,

* Similarly, bonds guaranteed by counties, a procedure not at all uncommon in the Southern States in railroad promotion, have no place in a valuation for rate-making purposes.

Mr. James.

such values should continue to be recognized in stating or approximating the original cost; but any law regulating valuations of future properties should rigorously exclude such values. For, obviously, such special values do not attach to the land; they come into existence in the land only when the utility enters upon it. The Committee's stand in this matter is undoubtedly right.

When the question of excess or deficiency of past earnings is considered, our attention is again directed to the advantage of emphasizing some principles that should control in establishing methods of valuation for rate-making. The Committee suggests that deficits occurring in the development period, if covered by the producers, should be capitalized, and this suggestion is well founded; but, if such deficits are made a basis of future dividends to the corporation, why, on the other hand, should not past excess earnings go to offset such development deficits? Surely, if the earlier records, covering transactions and financial conditions during the first years of existence, are to be considered adequate as a basis for determining development costs, then subsequent records, for years when organization has improved and crystallized, may properly and reasonably be considered adequate to determine the excess earnings.

Two very interesting matters are presented for consideration by the Committee relative to efficiency of operation and special advantages in site or conditions of production. No definite suggestions are advanced, however, with the view of introducing these elements into a physical valuation, beyond a general recommendation that they receive due consideration at the hands of the Courts and of the regulatory commissions. The second of these questions is one of economic rent, and has all the difficulties attaching to such. It involves the really serious question as to what poorer, less efficient organizations are to do, if rates are adjusted for highly efficient competitors in the same territory. In the nature of things, the poorer road would lose business unless it meets the competition. On the other hand, there is a serious situation created if rates are adjusted for the efficient road so that when applied to the inefficient road adequate revenues will be produced to operate and pay returns. There is a solution, but no one known to the writer has had the temerity to suggest it in this connection. The solution is to adjust rates to make the less efficient or less favorably located road pay the minimum return. Adopt a sliding scale of fair returns and permit the stronger road to charge the same rates as the weaker and pay to the State, in form of taxes, all but the necessary revenues to operate and pay a fair return according to the sliding scale. The higher permissible rate would then save the weaker road, and be sought by the stronger, and the sliding scale would preserve the required incentive to increased efficiency in the case of both, and prevent excess earnings.

Mr. James.

Obviously, such matters are due for serious consideration at a much later time, when regulatory methods are more advanced than at present; but such problems are certain to demand solution sooner or later. Those analysts of the present situation who are most disinterested, who see the tendencies of our time writ large and growing imperatively to demand a stronger control, do not hesitate to declare that the success of democratic government depends on greater discipline, more restraint, and fairer adjudication in all the relations of large-scale production with the general public.* Such control is not impossible. It exists in some nations of Europe. Such discipline as may be necessary does not necessarily destroy the incentive to save and invest, for a much severer discipline in Germany and Austria than will be developed here in many years does not do so.

The great question left is that of a fairer adjudication. This demands action in our time, change from present conditions; and all change hurts. The railroads constitute undoubtedly the greatest single development in the economic life of the western hemisphere. They are largely responsible for the general industrial development of the United States, and have played no small part in producing the seriously perplexing questions of regulation of public service companies. It would be a national disaster to hamper the railroads by a maze of restrictions regarding their operation, and great care must be exercised in this respect. Some States have already, doubtless, gone too far. Railroad operating managers are more expert in such matters than legislators; but control and supervision of railroad finances must be accepted as imperative. Such control is eventually to be continuous, and, in moving toward it, the chief consideration should be given to the principles underlying the elemental relations of the public and the corporations. Past wrongs must, so far as possible, be righted; but that no complete adjustment is possible is generally recognized. The greatest good can no doubt be effected by sane constructive legislation providing for control. On the success of this movement rests no inconsiderable part of our future national prosperity and progress. Engineers, as managers and as men of affairs, are wonderfully well equipped to handle these problems, and can hardly give them too much attention.

Mr. Sparrow.

W. W. K. SPARROW, ASSOC. M. AM. SOC. C. E. (by letter).—This report is most complete and exhaustive, and is certainly a very valuable addition to the literature on this subject. The Committee deserves the thanks, not only of the Society, but of all persons interested in the valuation of public utilities, for the time and thought it must have given to the preparation of such a report, covering as it does prac-

* "Principles of Economics," F. W. Taussig, Vol. II, Chapters LX to LXIII.

Mr. Sparrow.

tically all the basic and fundamental principles underlying the valuation of public service corporations.

The writer has not had the time to digest the whole report thoroughly, and will confine himself at present to the question of development expenses and land values.

The Committee defines the term "Development Expenses" as "the investment necessary to put the plant into successful operation and to create revenues that justify its construction," and prefers to use this term to that of "Going Value." The writer fully agrees with the Committee that the term "Going Value" has been given so many interpretations by the Courts and others that it is pretty generally misunderstood, and its use is inadvisable.

The Committee is of the opinion that, except in the case of a losing venture, the development expenses, as already defined, should be included in the cost of the property. The writer has given some thought and study to this question, and is not in agreement with this recommendation. It is understood at the outset that the report of the Committee, and therefore any discussion on it, relates to valuation for the purpose of rate-making only.

Development expenses may be divided into two classes:

(1) Expenditures made to create or attach business;
(2) Loss of dividends, and loss due to the earnings being insufficient to pay operating expenses.

The principle involved in the Committee's recommendation is that such expenditures as are classified in the first division and such losses as are classified in the second division constitute a property investment in the business, and that as such the general public is required to pay a return on this investment, or, in other words, that the company is entitled to capitalize such expenditures and losses on the same ground that it is entitled to capitalize interest paid on capital during construction.

Does any live well-managed property ever reach the point in its life when it is not necessary for it to expend large sums in developing and acquiring new business? On the contrary, is it not true that the larger and more prosperous a business becomes, the larger these expenditures become? Has any one ever heard of a company charging such expenditures to capital account and asking a long-suffering public to pay a return on such investment? Such expenditures are universally recognized and treated as a part of the operating expenses, and the writer can conceive of no good or logical reason for treating such expenditures, made at the beginning of the life of a business, in any different manner than that in which they would be treated if made during any other period of the life of the business. They are operating expenses

Mr. Sparrow.

first, last, and all the time. Recognizing this fundamental principle, the next point to consider is whether a company is entitled, as a legal right or in reasonable equity, to capitalize deficits in its operating expenses incurred during the first few years of its life. If such deficits are capitalized and treated as part of the investment of the company on which the public must pay a reasonable return, it logically follows that the return for depreciation, which is based on the total investment, will be increased in proportion to the amount of these losses, and, as a result, the public will in time, not only amortize such losses, but continue to pay a return on them.

The writer is not aware that any Court has laid down the principle, which this recommendation of the Committee involves, that the public should guarantee a company against loss from operation, and he doubts if such a principle will ever be adopted, but he feels sure that no Court will ever lay down the principle that such losses constitute a legal investment in the business of the company on which the public is obligated to pay a return. Although refusing to admit the principle that the public is obligated to refund the losses of a company made in the first years of its life, the writer believes that where a company, in the prosecution of legitimate business, has contracted losses in the starting of its business, or where the returns have been insufficient to pay a fair return on the investment, and the company can conclusively prove that it has not recouped such losses in later years, it would be fair and just in fixing the rates to make the return such that the company would be recompensed for such losses. In other words, the writer cannot conceive of such losses as an investment in a plant or business, but thinks that it is a condition which may justify a higher rate than would have been the case had no such losses been incurred, until such losses have been amortized.

The writer considers that if the principle were adopted that the deficiency, representing the difference between the amount actually earned and the amount which the corporation is entitled to receive, under the basic principle that it is entitled to a fair return on the fair value of its property, is to be capitalized and treated as an investment on which the public shall pay a fair return, then, as a corollary, the surplus, representing the difference between the amount actually earned and the amount which the corporation is entitled to receive under the same basic principle already outlined, should not only be returned to the public, but the corporation should continue to pay the public a fair return on this amount. The writer believes that on past records the public could well afford to adopt this principle.

Land Values.—In view of the physical valuation of the railways in the United States, which is about to be made by the Interstate Commerce Commission, this question looms up very large, and to

Mr. Sparrow.

the writer's mind overshadows all other questions in the valuation of public utility corporations. The tremendous importance of the question can be better appreciated by a reference to one or two recent cases involving this question. In the Minnesota Rate Case the total original cost to the Northern Pacific Railway Company of the terminal properties in Minnesota was $4 527 229. The Master in the United States Circuit Court allowed a value of $17 315 869. The total original cost of the entire system was found to be a little more than $312 000 000, but the cost allowed by the Master on the reproduction basis was more than $452 000 000, the difference, $140 000 000, being principally the increased value of the land.

In the Western Advance Rate Case, the Burlington claimed a return on a present value of $530 000 000. Commissioner Lane found that the amount of the original investment was only $258 000 000, and that about $150 000 000 of the Burlington's claim represented increase in the land values.

In the appraisal of the Northern Pacific Railway by the Washington Railroad Commission, H. P. Gillette, M. Am. Soc. C. E., Consulting Engineer to the Commission, placed the original cost plus improvements at $75 457 893, and the cost of reproduction new at $103 613 442. The difference is mainly due to the increase in the value of land.

These cases are only typical of many others, and they illustrate powerfully the magnitude of the question under discussion.

The claim on which the right to capitalize the increased value of the land is based, is that the practice in recent years has been in favor of the reproduction cost less depreciation, and that the fair value on which the return is to be made is the present value rather than the original cost, and that, on this basis, land must be treated in the same manner as the other property of the corporation.

If we study the history of valuation methods and Court decisions, it is easy to see how the reproduction cost or present-value theory came to birth. In the first cases which came before the Courts, the utility corporations claimed a return on the amount of stocks and bonds outstanding, which, it was argued, represented the original cost plus improvements, or the investment in the property. The Courts appear to have seen very clearly that to allow a return on such a basis would be unfair, for the very reason that such stocks and bonds in many cases included water, and did not represent the investment in the property. At this time there did not appear to be any difference of opinion in the minds of either the corporations or the Courts that the return should be based on the investment, and the only reason for the Courts' refusing to allow a return on the outstanding stocks and bonds was that they did not represent the *bona fide* investment. In searching for a way out of the difficulty, the reproduction-cost and present-value methods were devised. At the time it does not appear to have been

foreseen by the Courts that in avoiding the frying-pan they may have fallen into the fire, and that much greater injustice may be done the public in the application of these theories to the unearned increment of land. Mr. Sparrow.

Land differs very materially from the other property of a utility corporation for the reason that it seldom if ever depreciates. There may be times when the value of land does not increase, but, if taken over any considerable length of time, it will in nearly all cases increase. In the case of a utility corporation, it will invariably increase, and that enormously. Here, therefore, the application of the reproduction theory is very one-sided, and is as correspondingly unjust to the public as it is advantageous to the company.

It is recognized and accepted beyond further argument that the consumer must pay such a return to the company as will cover the amount of the depreciation of the company's property. This being so, and the consumer being debited with the amount of depreciation, he must, as a matter of substantial justice, be credited with the amount of the appreciation.

This contention is supported by the general rule laid down by Judge Hough of the United States Circuit Court in the case of the Consolidated Gas Co. *v.* City of New York. Judge Hough says in part:

"Upon reason, it seems clear that in solving this equation the plus and minus quantities should be equally considered, and appreciation and depreciation treated alike. Nor can I conceive of a case to which this procedure is more appropriate than the case at bar."

Commissioner Maltbie has attempted to consider appreciation in value as income, canceling it against depreciation in other property, but the writer believes that the same result would be arrived at more logically and with greater simplicity by appraising the land at its original cost. The railroad is a public servant. It has been thus defined by the Supreme Court, but the writer prefers to consider it as the agent of the public.

In the case of Smyth *v.* Ames, Mr. Justice Harlan says:

"A railroad is a public highway, and none the less so because constructed and maintained through the agency of a corporation deriving its existence and powers from the state. Such a corporation was created for public purposes. It performs a function of the state. Its authority to exercise the right of eminent domain and to charge tolls was given primarily for the benefit of the public."

To the writer, the answer to the whole question is contained in this weighty and forceful declaration. If a railroad company or other public utility is the agent of the State, performing a function of the State, and in that guise is vested with a governmental authority to acquire land for the purpose of serving the public, can this fundamental relationship, to which the company owes its very existence, now

Mr. Sparrow.

be thrown aside, and the agent demand from the principal the increased value on the land it was allowed to acquire for the purpose of serving and benefiting the principal.

The land was never granted to the railroad company for real estate speculation. It was granted for one purpose only—railroad purposes, and for the benefit of the public.

If the rate is insufficient for the service performed, and does not yield a fair return on the money devoted to that service, then it is an argument for an increase in that rate, and, in justice to the company and in the interest of the public, the rate should be increased; but, if the rate is sufficient for the service performed and does yield a fair return on the money invested, then can it be considered as an argument for an increase of that rate that the real estate has increased in value and a further toll be imposed on the public to whose service this real estate was dedicated?

The writer is strongly opposed to Government ownership of public utilities, but he is a firm believer in Government ownership of land, and that the Government, State or Federal, as the case requires, should acquire all land necessary to the construction and operation of a public utility and lease such land at a fair return on the cost of acquiring it to the company, such rental being charged to the operating expenses of the company and paid by the consumer. If such a principle had been adopted from the start, the question of the unearned increment could never have arisen, as the increase in value of the land would have been credited to the account to which it rightfully belongs, that of the public.

Mr. Wilgus.

WILLIAM J. WILGUS, M. AM. SOC. C. E. (by letter).—Although the writer has the gratification of knowing that the views expressed in his recent* paper on the physical valuation of railroads are substantially in accord with those contained in this very complete and admirable report, he finds himself unable to agree to the proposition that, for rate-making purposes, depreciation should be deducted from the cost of reproduction new.

The Committee considers that depreciation should be divided into two classes, the first consisting of low-cost and shorter-lived items of property to be repaired or replaced through charges to current expenses; and the second consisting of high-cost and longer-lived items of property, to be renewed through charges to capital.

Therefore, apparently, it is the intention of the Committee that the first class is to be treated as an operating expense and the second class as a restoration of capital to the investor.

If this is a correct understanding of the Committee's position, the sum that it proposes shall be taken as the basis for rate-regu-

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 203.

lation is not "cost of reproduction new less depreciation," but rather "cost of reproduction new less the portion of depreciation that applies to high-cost and long-lived items." In this event, the portion of depreciation that is to be taken care of through current expenses is not to be deducted from cost of reproduction new. Mr. Wilgus.

Even though common practice and the rules of regulatory commissions should permit the charging of replacements of a large nature to capital account, which they now expressly prohibit, it is difficult to see how in practical every-day railroad accounting and maintenance it will be possible to draw a well-defined line between the two classes of depreciation.

The Committee says:

"As a general statement, it may be said that the basis of expectation of life should be used for all important items of property having a life of more than, say, five years, except where it may involve unwarranted expense for accounting or be impracticable to separate what would properly be, under the Equal-Annual-Payment Method, charges to current expenses and to capital."

The writer believes that on railroads with their vast multitude of parts of varying and uncertain lives, the exceptions mentioned would prove the rule and the plan would fall. Rails and ties on sharp curves or of inferior material or subjected to heavy traffic, may have a very short life, though at other places less exacting conditions will make for a greatly lengthened life. An increase in the weight of motive power suddenly may cause bridges to become obsolete, whereas a change from steam to electric locomotives, with their lessened weights, may as sharply reverse the situation. Buildings and wharves under certain circumstances or policies may be continued in use indefinitely, through repairs and remodeling; and under other conditions may be replaced with new structures; or they may be abandoned. The instances may be multiplied *ad infinitum* to show that the drawing of a line between the two classes of depreciation would prove to be impracticable.

With the admission by the Committee that, because of certain difficulties, only a portion of depreciation may with propriety be deducted from cost of reproduction new, the grounds for asserting as a principle or fact that a depreciation allowance is a return of a part of the investment would seem to lose force.

The crux of the question appears to lie in the requirement of the Interstate Commerce Commission and the various State regulatory bodies that upkeep shall be charged to expenses and not to capital. As long as this situation continues, depreciation plainly is a liability of the owner to be replaced by him out of the allowance made for that purpose in the rate, or in case of misuse of such

Mr. Wilgus.

allowance, to be made good by him out of the part of the rate assigned to him for profit.

In this connection, sight should not be lost of the impossibility of maintaining a railroad in a new condition. A well-maintained property in time reaches an average condition, say, 85% or 90% of new, which remains practically stationary. In such cases an appraisal with depreciation deducted will show a loss of value, though, as a matter of fact, the real worth will be greater. For instance, no one will deny that the Pennsylvania Railroad between Jersey City and Philadelphia is more valuable for the purpose for which it is used, than a brand-new unseasoned parallel line having the same physical characteristics. Depreciation in cases like this is merely a measure of the cost of securing a seasoned railroad and may be considered as belonging in the same category as other legitimate overhead expenses.

The importance of this depreciation question is so great that it is to be hoped that the Society will not lightly lend its sanction to any view that will not successfully bear a critical analysis.

The Committee considers that adaptation and solidification should have no place in the valuation, unless they have involved the expenditure of money. As no such rule is proposed in the cases of donations of right-of-way and other property, it hardly seems logical to exclude the enhanced value that comes with time to the seasoned railroad, nor does this course seem equitable when the stand is taken that depreciation due to the action of the elements and natural causes shall be deducted.

Mr. Gibson.

J. E. Gibson, M. Am. Soc. C. E. (by letter).—The Society is fortunate in obtaining this valuable report, and the gentlemen composing this Committee are to be congratulated on their thorough and painstaking work. It is to be hoped, however, that the Society will give careful consideration to this report and before presenting it to the public as its report, will consider every phase of the matter, so that all parties in the proposed valuation, if conducted under the Society's rules, will have justice and equity. Undoubtedly, any rules that the Society may formulate for procedure in valuation cases will carry great weight with the public and the Courts. The report, the writer believes, does not insure complete justice and equity to the privately owned utilities.

The report is very comprehensive, but there are several points on which the writer cannot agree with its conclusions. It has running through it that deference and awe that all have for the majesty of the Court. The writer does not in all cases share this deference, as he recognizes the Court at best as only human, and as likely to err as others. Necessarily, the Court lives in the past, and its actions are controlled by precedent, whereas the engineer must of necessity

Mr. Gibson.

be a pioneer and establish his own precedents and landmarks. This being the case, the Courts have erred unintentionally and honestly in many of their decisions in the valuation of public utilities. To correct these conditions and to place before Courts and commissions proper rules for procedure is one of the functions of the members of this Society. Men trained in engineering subjects and having wide engineering experience in construction, in conjunction with men trained in financing and operating public utilities are certainly more competent to pass on the valuation of these utilities than those trained in the law, such as the Courts.

Purposes of Valuation.—The Committee states in one of the opening paragraphs of the report as follows:

"It is sometimes held that valuations for all of these purposes should give identical results. This view cannot prevail if the laws of the different States and certain decisions of the Courts are complied with."

It seems to be a common belief that the value of a property depends on the purposes for which the valuation is made, but the longer this is considered the more one is forced to the conclusion that the true value of a property is independent of the purposes for which the valuation is made. If this premise be correct and the decisions of the Courts and the laws of the various States are antagonistic to these premises, then it is our duty as a body to take all reasonable and just measures to modify and correct the laws and decisions of the Courts. The value of a property for the purposes of sale should be the same as that for the purpose of rate-making or taxation; for, should the purpose be that of sale, and a sale be consummated on the valuation made, then the new purchaser should be entitled to receive a proper return on the purchase or valuation price, and this return, in justice to all parties, should be neither greater nor less than that on the valuation of the property before sale for rate-making purposes.

It is realized that a property may have a sentimental value, but no purchaser is willing to pay a greater price because of such sentimental value. On the other hand, under certain conditions, a purchaser will pay more than the apparent real value of a property owing to a latent or potential value, which, by his business ability or connections, he can transform to an active value, but, in so doing, he converts the latent value to the uses of the public, and is therefore entitled to a proper return on this increased value.

The Committee touches on what would be termed the negative phase of this latent value where it speaks of a property, which, under certain abnormal conditions, may never be able to earn a fair return on the investment, and says "such a property may be classed as a losing venture". In valuing a property, should it have a latent value

Mr. Gibson.

due to strategic position or other natural facilities, this value should be added to the physical value, the same as an appreciation in the value of its real estate, and, on the other hand, by unfortunate location, wasteful construction, or otherwise, should the property be unduly expensive, then this inherent and excessive cost should be deducted from the valuation, the same as depreciation on the physical plant would be treated.

Methods of Determining Physical Value.—A board of public utility commissioners or engineers should strive to place themselves in the position of the original builders at the time the plant was conceived. It has been the writer's observation that with but few exceptions all engineers and contractors are optimists, and are always willing to undertake to do for less money, and in a shorter time, more work than they can actually perform. Therefore, in valuing an existing plant, and notwithstanding that they have a life-size plan of the work to be valued, the appraisers are more than likely to lose sight altogether of the contingent expenses and items that go to make up a completed whole—such as the difficulties of labor, non-delivery of machinery, conditions of weather, difficulties of financing, and the other multitudinous delays that occur in the construction of extensive works. They should always be very liberal in their estimates and criticisms of the property, and give the benefit of every doubt to the owner of the property. To this end they should use great care and diligence in reaching their final conclusions, and, for this purpose, should always seek the advice and counsel of men who have had experience and training in the actual construction of such works. It is obviously unfair to ask a railroad engineer to pass on the cost of a water-works property. He (the railroad engineer) would unintentionally, but honestly, undervalue an embankment for reservoir purposes, as the methods of construction are entirely different, and, in the same manner, it would be unfair to the railroad property to ask a water-works or hydraulic engineer to value a railroad property. It seems, however, to be the practice of most of the present public utility commissioners to employ one chief engineer and expect him to pass on all classes of utilities. This procedure, in a great many cases, works an injustice on the majority of the utilities in the State. Again, on account of the niggardly policy of some of our legislatures in the payment of its officers, the commissioners are very often compelled to accept the services of men who have not had the necessary experience in the actual construction and operation of public utilities, and therefore do not realize the cost of performing satisfactory service.

Unused Property.—This is a rather difficult subject, but if the property that is not in use has been purchased with a view of future extensions and use, and this future use or extension will be required

Mr. Gibson.

within a reasonable time, the company is entitled to a return on this property; and, in line with this reasoning, a public utility is entitled to a return on a plant which is built larger than the immediate needs require. Of course, the appraisers should use their discretion as to whether this unused property or over-built plant is beyond the reasonable requirements and needs of the future, but, even in this case, the utility should be given the benefit of the reasonable doubt. A water-works utility company, for instance, is certainly entitled to construct a plant of sufficient size to meet the public need for a period of at least 10 years in advance of the immediate requirements, and any outlays of money looking toward the extension of its piping system, pumping facilities, or water supply, with this object in view, are certainly within legitimate business requirements, and one which the public should demand of the utility.

Present or Original Conditions.—The board of appraisers, in considering the present conditions of the plant, should also consider the conditions existing previous to the commencement of construction; otherwise, the utility might be done a great injustice.

The writer does not agree with the Committee regarding the increased value of the plant due to public improvements, etc. Under existing laws, the holder of real estate or other property is entitled to the unearned increment of value from his property, and the same should hold for a public utility. Because the utility has been given something outright does not relieve the public from paying a fair return on this property, provided it receives the benefit of the use of the property: Because A buys an auto truck for $10 000, and then turns it over to B for nothing does not impose on B the operation of this truck for the benefit of the public without a return. This is a parallel case to that of a public utility which has had service connections and rights of way donated to it, or that of the public constructing highway improvements in its territory. The writer, however, believes that the service connections of the patrons should be put in at the expense of the utility, and the utility should be permitted to carry this charge as a capital charge, the same as for any other portion of the property. It is unfair to exclude the cost of these improvements in the valuation of the plant for rate-making purposes, for, if the plant were being valued for sale, these items would enter into the valuation, and, therefore, should the sale be consummated, an injustice would be done the new purchaser, as he would not be allowed a return on these portions of the purchase valuation, which would defeat the purposes of the valuation for rate-making, namely, equity to the owner and equity to the public.

Reproduction Method of Valuation.—The writer can see no objection to the reproduction method of valuation for existing public utilities, and, for properties that have been constructed previous to

Mr. Gibson.

the last decade, it is probably the only method that can be adopted satisfactorily. In the hands of engineers of experience and judicial temperament it will give a valuation equitable to all parties concerned.

The writer cannot fully agree with the report as to the propriety of deducting the depreciation on the existing plant. If the plant has earned a competent return sufficient to pay interest charge, operating expenses, and depreciation, then it is entirely proper to reduce the reproduction value of the plant by the amount of the depreciation; but, should the plant not have earned a competent return, but have gone along from year to year, paying only interest and operating expenses, it has done so at the expense of its vitality and due to its substantial construction. The public has received the benefit in low rates due to the plant's vitality, and therefore it is only just to the owner that he should be allowed to receive an additional return, which, on an amortization basis, would cover the accrued depreciation, at the time of valuation, at the expiration of the normal life of the plant. It is realized that this is not placing the burden on those who should have borne it, but it is the best that can be done; otherwise, the owner is compelled to put new capital into the plant to meet the demands of the public, or to suffer a total loss of that portion of his capital, or be willing to accept a return that is not a reasonable one. We are justified in placing this additional burden on the present and future generations by common consent; witness the issuing of long-term bonds for public improvements, etc.

Unit Prices.—The use of the average prices of material for periods of 5 or 10 years, ordinarily speaking, is fair, but occasionally there are times when this method would do an injustice to one of the parties. For instance, during the past few years, the price of cast-iron pipe has been as high as $36 per ton, and it is now approximately $24 per ton, a reduction of 25 per cent. A water-works property properly designed and constructed in 1906 and 1907, when pipe was selling at from $30 to $36 per ton, is just as capable of performing service as if constructed to-day; therefore, to value it on the price of pipe since 1907 would be an injustice to the water company, and then again, a plant constructed in 1898 when cast-iron pipe was down to $18 per ton, valued in 1906 at $30 per ton would be unjust to the public, so it is again seen that the judgment and discretion of the appraising board must be used if equity between all parties is to be obtained.

The writer believes that the prevailing rates for labor, during the previous 12 months, in the vicinity of the works that are being valued, should be used, as the rate of wages for labor is constantly increasing and will probably never be less than it is at present.

Mr. Gibson.

Overhead Charges.—The writer endorses fully the report with reference to the items of overhead charges, as with few exceptions, they are probably universally under-estimated. Preliminary promotion and engineering expenses are in a great many instances paid out of other resources than those of the company, and, due to the optimism of the engineers, the preliminary and organization expenses are grossly under-estimated. The writer ventures to state that very few engineers realize the actual cost of reproducing their plans and blue prints covering any extensive work. Their cost records in this department of their work are with few exceptions neglected.

Development Expenses.—In this the Committee gives a new term for an old one without aiding or elucidating the difficulties that have been met with in the use of the old term. The discussion of "going value", as applied to a utility, has probably covered more space in the proceedings of the various technical societies than any other single subject in recent years. Some claim that it is nothing but a guess; others that it is another way of expressing the deficits of the company that have accrued from the time of its completion to the date of the valuation. Charles Gobrecht Darrach, M. Am. Soc. C. E., argues that "going value" is a misnomer, and that the proper term should be adolescence, comparing it to the growth and development of a child from birth to manhood. Undoubtedly, an operating plant has a greater value than a non-operating plant, and whatever this value may be called, the utility is entitled to earn a return on it, as it represents an expenditure of capital or its equivalent. Whatever the term used for this value, the writer would define it as that value of an existing operating plant having consumers and revenue over and above the value of a similar plant in the same locality having the ability to serve but no consumers or revenue. This value is independent of whether or not the utility is earning a satisfactory return. It is a value, however, that is susceptible of quite a bit of variation, but if approached with an open and judicial mind, by appraisers of skill and experience in construction and operation, it will give equitable results to all parties.

Depreciation.—The writer regrets that the Committee finds it necessary to offer a new name for the depreciation allowance. It offers the new term, "Equal-Annual-Payment Method", which is just as difficult to explain as the sinking-fund method, and, if not read carefully, gives one the impression that it proposes to repay to the investor a portion of his capital annually and thereby reduce his interest return. The equal-annual-payment method is substantially the same as the sinking-fund method, except that the latter requires that the annual amount of depreciation be used in the business, and therefore, the writer would much prefer the term "Uniform-Investment-Charge

Mr. Gibson.

Method", used by Mr. Robert H. Whitten.* By this method the amount of the depreciation is put back into the works and bears the same return as the other portions of the capital, and the advantages are that it insures to the investor a constant one hundred cents on the dollar value in the property and at the same time permits the public to obtain a minimum charge for service rendered, as the amount of the depreciation of the original cost is reinvested in the property and is made to earn the same interest charge as the original capital.

The amount of this depreciation, however determined, should not be deducted from the value of the plant when fixing the rate of return to be allowed the utility, but only considered in determining the additional return to be allowed to cover the wear and tear, obsolescence, and inadequacy. It is obvious that, should the utilities be allowed only a return on the depreciated value of their properties, they could not meet their interest charges after the first year.

The writer's objection to any of these methods is the multiplication of terms and the difficulty in explaining to the investing public, and possibly the banker, the method proposed to be followed in allowing for depreciation, whereas the sinking-fund method is generally understood. The results obtained by either method are identical, provided the depreciation charge is put into the business and not returned to the original investor, or invested in outside securities.

The term "Uniform-Investment-Charge Method" by its name conveys the idea that the investment is maintained at a uniform value and that the charge to the rate-payers is uniform.

Appreciation.—The writer agrees with the Committee with reference to appreciation, notwithstanding the fact that quite a few recent Court decisions have viewed it differently. Certainly, if a utility asks for a return to meet depreciation, it is only fair to the public to grant them a return for any appreciation in the value of its works due to the growth of the community, etc.

Land Valuing.—Any engineer of experience in the promotion and construction of public utilities is fully aware of the appreciation in land value due to the knowledge that it is to be used by a public corporation. The owner of land, with few exceptions, on learning that his property is required by a utility or corporation, at once places an inflated price on it. Further, the prospective utility can afford to pay almost any price rather than proceed by law to condemn under the provisions of eminent domain, as the general public views all utilities as legitimate spoils. Of course, an owner of property is entitled to a reasonable valuation for the property taken, together with the consequential and severance damages, but, in the majority of cases, boards of jurors have taken a too liberal view and awarded inordinate damages. Therefore, a board appraising public utilities

*Ably set forth in *Engineering News* May 8th, 1913.

should be equally liberal in valuing the property of the utility, and for this purpose should consult with and obtain the views of real estate men having to do with the purchase of properties for the class of utilities being appraised. Mr. Gibson.

Rates Based on Physical Value Only.—The writer heartily endorses the opinion of the Committee that the rates should be based on other items than the bare physical value of the plant, and, in this line, thinks that it should certainly cover the rates on such intangible values as strategic location, efficiency, etc. He, however, does not believe that, because a utility has earned exceptional rates, due to its non-regulation by utility committees, it should continue to do so in the future, although justice to the innocent investors would require that their rates be reduced, not at one sweep, but rather on a sliding scale, so as to allow a sufficient time for readjustment.

Continuous Regulation by Commissions.—The writer agrees with the Committee that the regulation should be continuous and not spasmodic, but it absolutely fails to touch on the point of how often the regulation and readjustment of rates should be undertaken. In justice to the public and the investor, the rates should be adjusted to cover as long an interval as possible, and the writer had hoped that the Committee would make some recommendation as to the desirable interval between adjustments, as at present the companies can be made to defend themselves yearly before the commission. This means unnecessary expense and harassment to the company, deters public investors, and accomplishes no beneficial results. The Committee has not covered the question of the treatment of the expenses of financing, possibly thinking it was not necessary to do so. Neither does it discuss the question of intangible assets.

It has been generally decided that discount on bonds should be amortized. Therefore, in figuring the returns on the property, the interest rate should be increased to permit of this amortization fund. There is certain intangible property, which should also be amortized—such items as legal expenses, preliminary engineering, and promotion—for all these expenses ceased to exist at the expiration of the physical life of the plant, and a sufficient return should be earned so as to enable the utility to write these charges off its books at the expiration of a certain interval of time.

The Committee does not touch on the phase of the publicly owned utility, but seems to confine itself entirely to that of the privately owned. With few exceptions, the present laws of the various States have exempted the publicly owned utilities from regulation. This does a great injustice to the private utility. The latter is, to say the least, the agent of the State as much as the public utility, and therefore, though a publicly owned utility should not be permitted to earn a profit, it should be made to earn rates sufficient to cover

Mr. Gibson.

operating expenses, interest, and depreciation, and not be allowed to make up its deficits out of the general tax fund. If this had been made compulsory in the past, the public would more readily recognize the benefits that have been conferred on it by the privately owned utility.

Public utilities, by their immobility and the nature of their business, must of necessity be monopolies, and therefore, to permit duplication of utilities is the grossest kind of economical waste, and should not be permitted under any circumstances.

In conclusion, the writer had hoped that the Committee would adopt a definite nomenclature for the various terms used in valuations, giving clear and concise definitions of the terms used. This is one of the first problems that should be undertaken in formulating and standardizing a method of procedure on so great a subject as this.

Mr. Vensano.

H. C. VENSANO, ASSOC. M. AM. SOC. C. E. (by letter).—This report has been read with great interest. It should be of great value to all interested, and seems to go very thoroughly and clearly into all parts of the question. There is still, however, in the writer's mind, some doubt as to the proper method of handling depreciation.

It would seem to the writer, after going over this matter, that all methods thus far suggested become practically one after a number of years of application to a particular property. The only difference seems to be in the amount finally arrived at as the depreciation increment.

In substantiation of this, two tables are submitted: Table 1 is drawn up to correspond to the table on page 34 of the report, the only difference being that Table 1 has been made up on the basis of a property having an assumed life of 5 years. This is given for purposes of comparison with Table 2. A property having a life of 5 years has been used for simplicity and in order to shorten the calculations. Table 2 considers a complex property in which the annual depreciation increment can be at once reinvested. The left half of this table shows the remaining value of the property from year to year on which it is allowed to earn an investment return. The right half shows the depreciation increments reinvested each year in accordance with the Committee's suggestion that such "depreciation allowance" should be "treated as a part of capital and used for any purposes for which the corporation is authorized to use capital". Each column in turn then shows the depreciation allowances on the reinvestment of the preceding year's allowance. In the last column of the left half of Table 2 it is shown that the total value of the property on which interest is allowed to be earned has been maintained at $100, or its full original value, so that $5 is constantly being earned as an investment return.

In the final column on the right of Table 2 is shown the total depreciation allowance for each year. Mr. Vensano.

TABLE 1.—ILLUSTRATION OF EQUAL-ANNUAL-PAYMENT METHOD OF COMPUTING DEPRECIATION.

		$100.0000				

Assumptions: Property having 5-year life valued when new at $100. Computations of depreciation allowances based on 5% interest compounded annually. Annual return on capital invested at 5 and 7 per cent.

Particular attention is called to this right hand column, from which it can be seen that at about the fifteenth year's life of a property, the component parts of which have an average 5-year life, the annual depreciation allowance, under the equal-annual-payment method, so-called, has become constant and practically remains so during succeeding years. In other words, both investment return and depreciation allowance have become constant and we have arrived automatically at a straight-line or railroad method. The amount arrived at, of course, is different, but the method has automatically become the same. It is to be noted, also, that this is absolutely the same result that would be arrived at by following out the sinking-fund method, where the sinking fund has been reinvested in the property, so that equal rates of return have been obtained on the sinking fund and the original property.

In Table 2 the same rate of return, namely, 5%, has been allowed on both the original investment and in figuring the sinking-fund increment, and the writer does not agree with the Committee in advising that these rates be different, because it is apparent that, by reinvesting a sinking-fund increment in the property itself, the same rate of return as on the original property can be obtained.

Mr. Vensano.

ASSUMPTIONS:

Property, 5-year life.
Value of property when new — $100.
Depreciation allowance based upon 5 per cent.
Interest compounded annually.
Annual return on capital invested, 5 per cent.

Under Government regulation and fair adjustment of rates, such reinvestment should presumably be entirely safe, and should, therefore, without question, be entirely permissible.

In explanation of the construction of Table 2, it might be well to state that Column 22 is the depreciation return from year to year on the original investment. Column 23 assumes the reinvestment of the $18.10, which was the depreciation return for the first year, and shows the annual depreciation return on this $18.10. Column 24 then, similarly, shows the depreciation allowance on $19 (being the depreciation allowance on the original investment for the second year), plus $3.27 (being the depreciation allowance on the reinvestment of the first year, $18.10). Each column in turn then represents depreciation allowances on a reinvestment of all depreciation allowance accrued during the preceding year. The left side of the table, similarly, shows the remaining values for each year's reinvestment. These computations have been made with the slide-rule, and the sum of the items may not quite check with the required totals.

The writer feels that some confusion has obtained in the past in the handling of suggested methods of depreciation allowance because of

the apparent endeavor to fit them to the "necessary monetary reinvestment for depreciation" rather than to the "actual depreciation" itself. He believes that there should be a clear distinction between these two, depreciation being thought of rather as the actual inherent curtailment of life of the various parts of the property, whereas the monetary replacement requirements may be something very different.

In general, in a large and complex property, the true depreciation is very nearly a straight line, whereas the monetary requirements for replacement of its component parts may vary greatly. In general, for the first few years of life, such requirements would seem to increase from little or nothing upward, and gradually approach an average, although annually fluctuating above and below such average.

For instance, assuming a property in which the longest-lived single item would have a life of 10 years and would have other items of lives of 1, 2, 3 years, etc., up to 10 years. At the end of the first year the depreciation on the item of 1 year's life would be 100%; on the item of 2 years' life, 50%; on the item of 3 years' life, 33⅓%, etc. At the end of this year the item of 1 year's life, of course, would have to be replaced, and at the end of the second year we would again have 100% depreciation for the item of 1 year's life, 50% for the item of 2 years' life, 33⅓% for the item of 3 years' life, etc. At the end of this year the items of 1 and 2 years' life would have to be replaced, and would be so replaced. Thus, at the end of the third year we

Mr. Vensano. would again have the actual depreciation for each class of items as before. Now, note the variation in replacement requirements. At the end of the first year we must replace all the items of 1 year's life; at the end of the second year all the items of 1 and 2 years' life; at the end of the third year all the items of 1 and 3 years' life; at the end of the fourth year all the items of 1, 2 and 4 years' life; at the end of the seventh year all the items of 1 and 7 years' life.

For properties having parts of extreme lives, say 100 years, we might have replacement in the eightieth year, for instance, of properties of 1, 2, 4, 5, 8, 10, 16, 20, 40 and 80 years' life; whereas, in the seventy-first year, for instance, we would only have to replace the items of 1 and 71 years' life, showing a great range in the replacement requirements.

It might seem, therefore, that, considering the "actual depreciation", the straight-line method might work out most simply and still be entirely logical, the only objection being that, for the first few years of the property's life, a too high depreciation allowance would have been made to cover "monetary replacement requirements", but, as the property ages, the results obtained would be very nearly correct, as shown by Table 2.

Although making this statement, the writer still believes that the sinking-fund method is the preferable one, and should be used. Of course, he realizes that, because of Court rulings, rates must be fixed on depreciated property values, and the use of this method becomes somewhat difficult, but he thinks that by proper presentation of cases in future such decisions might be reversed and it might be allowed (where properties have been properly handled) to base figures for rate-making purposes on the undepreciated value of the original properties, and thus make this method usable.

The Committee's suggested method gives the same results, as previously stated, as the sinking-fund method, and the Committee has no doubt met the Court requirements, but, as just shown, it would seem that the same result could be arrived at by the straight-line method with less complications in the figuring of the depreciation allowances, and with a very material simplification of corporation accounting, which it would seem would become very complicated under the suggested method.

Mr. Crehore. WILLIAM W. CREHORE, M. AM. SOC. C. E. (by letter).—The writer is in accord with the Committee's views on all the important features of this report; the only suggestions he has to offer relate to matters of, perhaps, minor significance; but which, if modified, might be a greater force in convincing those who are opposed to the principles and methods outlined by the Committee.

Mr. Crehore.

Choice of Name.—As was well known, the real determination of the rate involves the whole theory by which a depreciation allowance is to be made. The Committee advocates what it calls the Equal-Annual-Payment Method, asserting that by its use the same results will be obtained as by the so-called Sinking-Fund Method, and then proceeds to show that, if depreciation takes place at a 5% compound-interest rate, the sum of the allowed depreciation during any one year and a 5% return on the remaining value of the property will provide a constant rate throughout the whole life of the property. The writer agrees with the Committee's theory of depreciation allowance, but thinks the adopted name, Equal-Annual-Payment Method, is a misnomer. Very great confusion has arisen in the past, as the Committee points out, from a misunderstanding of the difference between the Sinking-Fund Method, as such, and methods which make use of the sinking-fund curve. There seems to be no reason for this, except that the Committee's method and the Sinking-Fund Method both depend on a compound-interest rate of depreciation. Surely, many other things may depend on a compound-interest rate of change besides sinking funds, and just because a sinking fund does thus depend for its values from time to time is no good reason for not using a compound-interest rate when desirable, without the accompanying thought of a sinking fund.

Another reason for rejecting the name, Equal-Annual-Payment Method, is that, as applied by the Committee, the name describes the the rate but not the depreciation allowance. The Committee, in its illustration on page 34, computes an amount, $3.02, as the first year's depreciation, and then states that if this amount is allowed for depreciation in each succeeding year there can be added to it each year 5% interest on the original investment, and the two together will provide a constant rate. This is an imaginary situation which will never exist after the first year, and the Committee then proceeds to explain that, although the depreciation will take place like a compound-interest calculation, yet the return on the remaining value of the property will follow it on down, so that the sum total will always be a constant rate. According to this, then, the compound-interest curve is the real theoretical depreciation line, and not the Equal-Annual-Payment line at all. Why, then, should not this method be called the Logarithmic-Curve Method? As the compound-interest curve is a logarithmic curve, this name will exactly describe the theory on which the depreciation is computed, whereas the Committee's name does not.

There is still another reason for getting away from the name, Equal-Annual-Payment Method. The Sinking-Fund Method calls for equal annual payments also, and thus the ambiguity arising from a confusion of the two will continue.

Mr. Crehore.

Logarithmic-Curve Method.—In Fig. 1 the Logarithmic-Curve Method is illustrated, all values being plotted from the Committee's table on page 34. The total rate, which is constant at value \$8.02 (the top of the diagram) is made up of the two parts, one above, and the other below, the Depreciated-Income Line, *DPE*. This line follows the values given in Columns 3 and 4 of the table on page 34, so that, at any time during the life of the property, the ordinate, *MP* (above the curve), will represent the depreciation during the current

SINKING-FUND METHOD
SHOWING DISTRIBUTION OF THE RATE

FIG. 2.

year, and the ordinate, *PN* (below the curve), will represent the return on the remaining value of the property for the same year. This Logarithmic Curve, then, divides the rate at all times according to the theory advanced by the Committee for the treatment of depreciation. The Committee's imaginary line of equal annual payment is seen at *DF*, running horizontally.

Sinking-Fund Method.—The statement that the recommended method gives the same results as the so-called Sinking-Fund Method is only partly true so far as only the items of annual depreciation

Mr. Crehore.

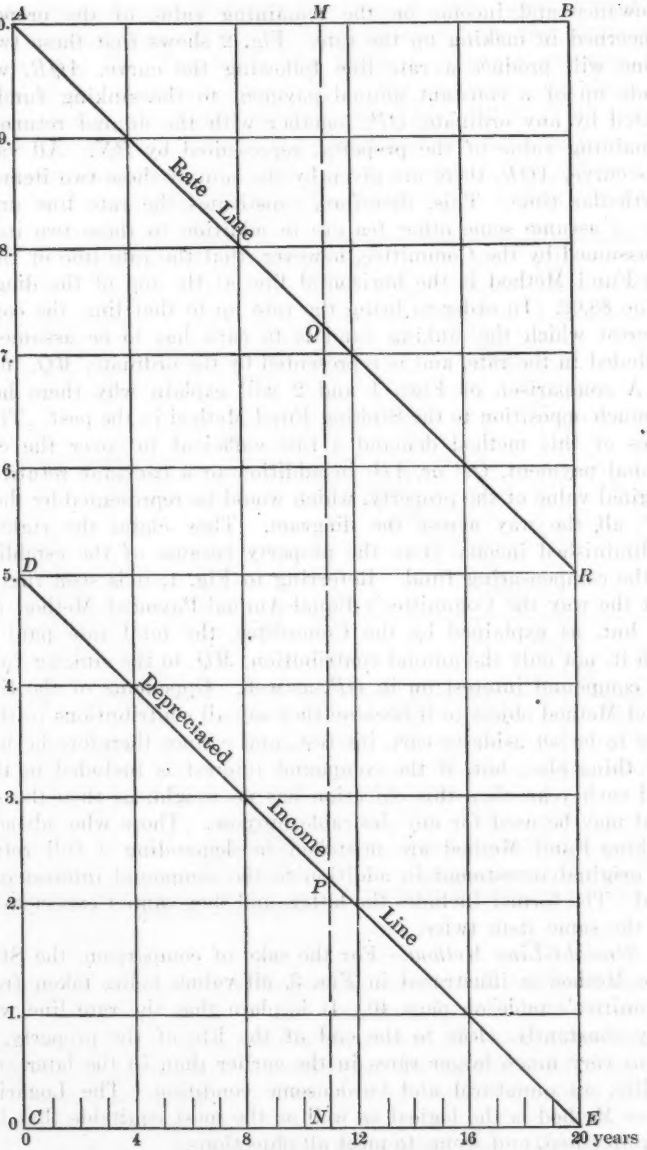
allowance and income on the remaining value of the property are concerned in making up the rate. Fig. 2 shows that these two items alone will produce a rate line following the curve, *AQR*, which is made up of a constant annual payment to the sinking fund, represented by any ordinate, *QP*, together with the annual return on the remaining value of the property, represented by *PN*. All values on this curve, *AQR*, then, are given by the sum of these two items at any particular time. This, therefore, constitutes the rate line unless we are to assume some other feature in addition to these two items. It is assumed by the Committee, however, that the rate line of the Sinking-Fund Method is the horizontal line at the top of the diagram at value $8.02. In order to bring the rate up to that line, the compound interest which the sinking fund is to earn has to be assumed to be included in the rate, and is represented by the ordinate, *MQ*, in Fig. 2.

A comparison of Figs. 1 and 2 will explain why there has been so much opposition to the Sinking-Fund Method in the past. The advocates of this method demand a rate sufficient to cover the constant annual payment, *QP* or *AD*, in addition to a constant return on the original value of the property, which would be represented by the value, *DC*, all the way across the diagram. They claim the right to an undiminished income from the property because of the establishment of the compensating fund. Referring to Fig. 1, it is seen that this is just the way the Committee's Equal-Annual-Payment Method is made up, but, as explained by the Committee, the total rate paid carries with it, not only the annual contribution, *MQ*, to the sinking fund, but the compound interest on it, *QP*, as well. Opponents of the Sinking-Fund Method object to it because they say all contributions to the fund have to be set aside to earn interest, and cannot therefore be used for any thing else; but, if the compound interest is included in the rate paid each year, then this objection has no weight, as then the sinking fund may be used for any desirable purpose. Those who advocate the Sinking-Fund Method are mistaken in demanding a full return on the original investment in addition to the compound interest on their fund. The former includes the latter, and they cannot expect to charge for the same item twice.

Straight-Line Method.—For the sake of comparison, the Straight-Line Method is illustrated in Fig. 3, all values being taken from the Committee's table on page 40. It is plain that the rate line will fall away constantly, clear to the end of the life of the property, which means very much larger rates in the earlier than in the later years of its life, an unnatural and burdensome condition. The Logarithmic-Curve Method is the logical as well as the most equitable that has yet been proposed, and seems to meet all objections.

Logarithmic Curve of Depreciation.—In Fig. 4 is illustrated the curve of depreciation itself, based on the Logarithmic-Curve Method.

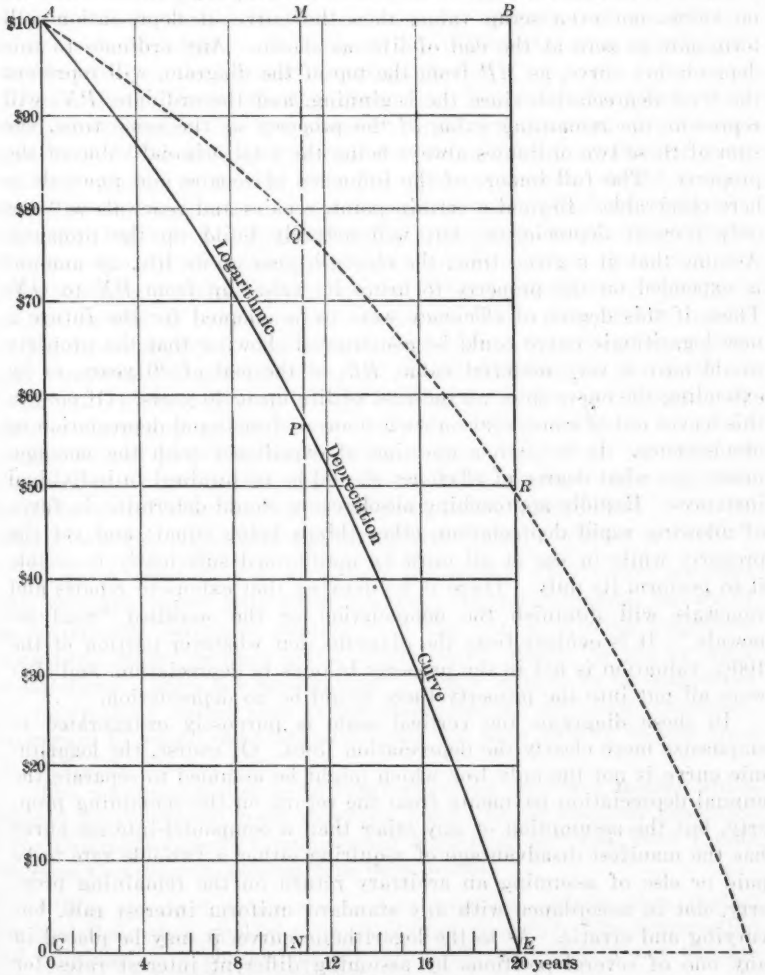
Mr. Crehore.



STRAIGHT-LINE METHOD
SHOWING DISTRIBUTION OF THE RATE

FIG. 3.

Mr. Crehore.



LOGARITHMIC-CURVE METHOD
SHOWING ASSUMED DEPRECIATION

FIG. 4.

Mr. Crehore.

The upper horizontal line of the diagram, *AB*, represents the full value of the property at which the depreciation curve starts in the first year. If it be assumed that at the end of the property's life it will have no value, not even scrap value, then the curve of depreciation will terminate at zero at the end of life, as shown. Any ordinate to this depreciation curve, as *MP* from the top of the diagram, will represent the total depreciation since the beginning, and the ordinate, *PN*, will represent the remaining value of the property at the same time, the sum of these two ordinates always being the total original value of the property. The full import of the influence of repairs and renewals is here observable. Beyond a certain point, repairs and renewals will not only prevent depreciation, but will actually build up the property. Assume that at a given time, the eleventh year of its life, an amount is expended on the property to bring its value up from *PN* to *QN*. Then, if this degree of efficiency were to be adopted for the future a new logarithmic curve could be constructed showing that the property would have a very material value, *RE*, at the end of 20 years, or by extending the curve show an increase of life up to 30 years. Of course, this leaves out of consideration such items as functional depreciation or obsolescence. It is often a question of expediency with the management, just what degree of efficiency should be maintained in individual instances. Rapidly approaching obsolescence would determine in favor of allowing rapid depreciation, other things being equal; and yet the property while in use at all must be maintained sufficiently to enable it to perform its duty. There is no denying that extensive repairs and renewals will diminish the depreciation or the so-called "final renewals." It is evident from the diagram that whatever portion of the 100% valuation is not in the property belongs to depreciation, and if it were all put into the property there would be no depreciation.

In these diagrams the vertical scale is purposely exaggerated to emphasize more clearly the depreciation lines. Of course, the logarithmic curve is not the only line which might be assumed to separate the annual depreciation payments from the return on the remaining property, but the assumption of any other than a compound-interest curve has the manifest disadvantage of requiring either a variable rate to be paid or else of assuming an arbitrary return on the remaining property, not in accordance with any standard uniform interest rate, but varying and erratic. As to the logarithmic curve, it may be placed in any one of several positions by assuming different interest rates for each position, the position of no interest rate being of course the straight line itself. A curve of this sort is preferable to a straight line, for it is well known that most kinds of property depreciate more rapidly toward the end of life than near the beginning. The determination of the correct position of this line for a given item of property can and should be approximated by appraisals taken from time to time

or by knowledge previously gained from some similar item of property. Opponents of all theoretical methods of depreciation analysis deny their practicability, and claim that no theory can be made to govern the matter. It should be the endeavor of advocates of theoretical depreciation to adopt such a theory as will conform as closely as possible with practical results by appraisement. Mr. Crehore.

Payment of Depreciation a Return of Capital.—The Committee takes the strong position that these principal and interest payments, as depreciation allowances, are actual returns of capital to the corporation, and should be treated as such. These payments should be expended by the corporation only as capital is spent. Failure to observe this point has been the cause of many a financial catastrophe. Those having authority over public utilities should insist on this point, in order to prevent misleading the owners of the property as to their real income, as well as to protect the rate-payers from subsequent demands on them to supply, a second time, depreciation contributions which have previously found their way to the stockholders in the guise of dividends. If these payments have been properly reinvested as capital, then an inventory would be sure to include them, although the particular item of property, on which this depreciation money was paid to the corporation, might be appraised at its depreciated value. There could be no injustice in this transfer of capital expenditure from one asset to another. The injury always arises from the misuse of capital.

C. P. Howard, M. Am. Soc. C. E. (by letter).—The writer has read this very able report with great interest. As stated therein, the result is "a physical valuation, dealing with the cost of existing structures with little regard to their merit or efficiency", which, "is not by itself a satisfactory basis for rate-making". Other matters to be considered by rate-making bodies, such as favorable location, are briefly discussed, in regard to which the Committee "has not been able up to this time to formulate general rules". Mr. Howard.

The recommendation as to appreciation of land is a matter which should be considered most carefully before being accepted generally. The Committee quotes Commissioner Maltbie of the New York Public Service Commission, closing with these words:

"'Why should these matters be considered less definite when applied to land than when applied to the buildings thereon? The depreciation of buildings is a charge against operation; why should not the appreciation of land be a credit?'"

The answer to this question is obvious: The funds provided for depreciation are a part of the general expense of running the business —maintenance, repairs, and replacements. Replacements are, in a way, simply maintenance and repairs on a larger scale, and at longer intervals. Depreciation funds take care of replacements.

Mr. Howard.

The appreciation of land is entirely different. It has no necessary and direct connection with operation, or with the special use made of any particular piece of land. In a general way, of course, all industries in the community contribute to it. All other owners of property enjoy this increase as a clear bonus; the unearned increment. Why should the investor in a railroad be selected as the one of all others who shall not receive it? It is proposed to take from the corporation this benefit.

If the land increases in value, the rates to the public are to be correspondingly reduced.

The citizens of the community will enjoy, not only the increase in value of their own lands, which increase was created in part by the railroad, but also any increase in the value of the railroad lands, which sum in effect is to be taken from the company and distributed among them.

The man who buys a farm reaps his crops, and takes the profits. Any general increase in the value of land is his also. Why should it be different with a railroad company?

The Committee quotes from the decision of the United States Supreme Court in the Consolidated Gas Company case, in part as follows:

"'If the property which legally enters into the consideration of the question of rates has increased in value since it was acquired, the company is entitled to the benefit of such increase. This is, at any rate, the general rule.'"

If the corporation shall "in effect" pay "to the public the amount of the appreciation" as recommended by the Committee, what benefit will the company receive from such increase? Absolutely none.

DISCUSSION ON BITUMINOUS MATERIALS FOR ROAD CONSTRUCTION.*

BY MESSRS. W. H. FULWEILER, SANFORD E. THOMPSON, AND PRÉVOST HUBBARD.

Mr. Fulweiler.

W. H. FULWEILER, ASSOC. M. AM. SOC. C. E. (by letter).—The writer regrets his inability to be present to congratulate the Committee on the subject-matter and method by which it has collected and crystallized into concrete form so much of the recent development in the use of bituminous materials.

The use of such materials has advanced so rapidly during the past few years that naturally differences of opinion have arisen regarding the many details that enter into their utilization in road construction and maintenance. Many of these points have been covered by the Committee in such a manner that the writer believes that the report will be of the greatest practical benefit to many engineers, who, though they have been in charge of road construction, have been unable, through press of other duties, to give this subject the attention that it deserves, and who, therefore, have been frequently led into erroneous opinions. Relative to this matter special attention should be called to the Committee's statement regarding its conviction that there is no such thing as a "Panacea" for all highway ills, as the writer believes that at the present time there is a tendency on the part of some road authorities to insist on the use of a single type of construction under any and all conditions, which tendency has failed, and will fail, in many cases to result in the most economic type of construction.

*This is a discussion on the Report of the Special Committee on Bituminous Materials for Road Construction, for 1913, presented at the Annual Meeting, January 21st, 1914.

Mr. Fulweiler.

In connection with the use of the traffic census in deciding on the most economic type of construction, it is believed that more attention should be paid to the position of the proposed improved road in relation to the general system, and the effect of its improvement on the general direction of traffic.

For a number of years the writer has held the view, as expressed by the Committee, that the objectionable slipperiness of bituminous surfaces can be decreased or prevented by proper precautions during construction, and that the succeeding paragraph in the Committee's report points out one of the principal precautions to be observed, namely, to reduce the crown on roads constructed with bituminous materials to less than ½ in. per ft.

The protection of the edges of bituminous pavements is very important, especially in view of the fact that, where there is a considerable proportion of high-speed motor traffic, many of the older roads are so narrow that they do not permit sufficient clearance without the general use of the shoulder in passing. This point, however, is already beginning to receive attention in several States.

It is believed that the Committee might have dwelt even more strongly on the fact that the character of the stone must influence the choice or grade of the bituminous material to be used, and that, after all, the stone must eventually carry the traffic, and, though cementitious qualities in the stone are no longer necessary, the other desirable qualities of hardness, toughness, and low percentage of wear, seem quite as essential as in stone for water-bound construction.

The Committee's remarks on the maximum amount of distillate up to 170° cent. allowable in tars, reminds the writer of his professor in mineralogy, who, in his lectures, would, in describing the color of a mineral, proceed somewhat as follows: "The color is generally blue, frequently green, with yellow varieties quite common. Many red specimens have been found at Franklin, N. J., and a number of mines in Colorado produce quantities of black twins, while a translucent variety is widely distributed through portions of Pennsylvania."

It is especially gratifying to the writer to note that the Committee has set forth so clearly the necessity for care in the use of bituminous materials, in the paragraph, where it is stated:

"Whatever method of construction is selected, the use of a bituminous material by no means justifies any lack of care in the ordinary details to be followed, but rather increases the need for thoroughness and skilled supervision."

The writer believes that probably 70% of the failures which have been attributed to the bituminous material have been due, as suggested by the Committee, to lack of care in details and supervision.

The writer cannot agree with the Committee in reference to the question of the use or omission of a seal coat on bituminous pavements, as he believes that the seal coat, if for no other purpose than

insurance against incidental imperfection or carelessness in the surface treatment is always advisable, and that the sole cause for its omission should be lack of funds. Mr. Fulweiler.

The writer wishes to emphasize the thought of the Committee on page 4, where it is stated that: "Where the character of the traffic justifies the use of the bituminous concrete pavement, the same conditions demand an extraordinarily strong foundation therefor." Heretofore, it is believed that too little attention has been given to the question of foundations and their effect on the life of the surface.

The writer most strongly agrees with the Committee that hand-mixing methods should be avoided where practicable, and that, in the use of a heated aggregate in the construction of a bituminous concrete pavement, non-uniformity or excess in heating the stone should also be avoided. This practically recommends the use of some mechanical form of dryer and heater, which the writer believes to be essential for uniformly successful results.

In the Construction by Penetration Method, it is believed that an equally important factor for successful results is a thorough compaction of the road metal before the application of the bituminous material, secured by proper grading of the road metal. The writer believes that compaction will never be secured with stone of uniform size until a certain proportion has been crushed into chips, which, under the action of the roller, serve to key or lock the larger pieces together, and produce that mechanical interlocking which is necessary to stability. He also believes that this same stability can be secured with very much less rolling by the use of stone of varying sizes down to, say, ¾ or ½ in., and that such a stone mixture can be compacted with very much less rolling, thus resulting in a cleaner stone surface, and, therefore, better penetration and adhesion of the bituminous material.

In Construction-Surface Treatments, with which type the writer has probably had the greatest experience, he would suggest that the first paragraph read:

"The success of surface applications is proportionate to the penetration obtained by the bituminous material into the old road surface, and that such degree of cleanliness of the latter must be had, by sweeping or other methods, as will ensure the proper degree of penetration."

As the result of his experience, which would seem to indicate that penetration into the surface of the road is essential to success, surface treatment depending entirely on surface adhesion, even if it be perfect, will disintegrate by the failure of the water-bonding of the crust beneath the bituminous treatment.

From a careful study of a large number of roads, it has seemed to the writer that the most successful results have been attained where the penetration into the surface varied between ½ in. and 1 in. A

Mr. Fulweiler.

deeper penetration (1¼ to 1½ in.) was frequently indicative of too fluid a material, with the resulting deficiency in binding or bonding strength.

Too much stress cannot be laid on the cleanliness of the surface, as this is a fundamental requirement in successful surface treatment. The writer is also quite in accord with the Committee in disapproving of the use of fine sand, and in approving of the use of clean stone chips or small gravel for surface applications, and also in strongly disapproving of any excess in material.

He does not believe that under normal conditions the application of a bituminous material on a water-bound or bituminous surface is justified, unless it is covered with a mineral aggregate, as the cost of the latter is rarely 40% of the total cost of treatment, and he believes, therefore, that the rôle of the bituminous material in maintenance work is secondary to the stone, or rather mineral aggregate, and that its primary object is to protect the stone and assist in maintaining it in such a position that it may most efficiently and economically carry the traffic.

The next paragraph he believes should have the widest publicity, especially among many engineers to whom the care of the roads is but part of their work, and that is, that "the success of results depends first upon the condition of the surface to which the treatment is applied. Even the best surface treatment cannot correct defects in the original surface, though it may reduce or modify them."

Many cases have come to the writer's attention in which an improperly constructed, water-bound road had been given a light surface treatment with the expectation that such treatment would correct all the inherent defects of the original construction.

It is believed that the results obtained during the last two or three years would have justified the Committee in expressing its opinion on pressure distribution more strongly than it has. The writer's opinion, based on some four years' work with pressure distributors, and six years' observation of gravity distribution, is that with the use of pressure distributors, from 20 to 25% of material may be saved, 50% better penetration may be secured, and the over-all efficiency, as compared with gravity distribution, is about as two is to one.

So many discussions have recently appeared in the technical journals regarding the question of definitions, that the writer is rather loath to mention the subject, but he would call attention to the Committee's definition of "free carbon," and would suggest that "organic" be inserted before "matter," as bringing this definition somewhat more in line with the methods used for the determination of this constituent. It is not believed that the use of the term "free carbon" can be defended to any very great extent, as the material is not pure carbon, and the quantity varies with the method of determination and the solvent used. The writer believes it to be better practice to

use the term "material insoluble in," or "organic material insoluble in carbon bisulphide," without attempting to give a name known to be erroneous, to a compound or mixture of varying composition. Mr. Fulweiler.

Under "water-gas tars," the writer does not believe that the word "cracking" is used correctly in this connection, but that a more correct definition would be: "tars produced by the decomposition and polarization of oil vapors in the manufacture of carburetted water gas." The same criticism might be applied to oil-gas tar.

There are several points in connection with the report which the writer would like to discuss, but which he feels he should refrain from doing, as it would involve the discussion of characteristics that serve to classify certain commercial materials, and he does not believe that such a discussion by one interested in the commercial development of bituminous materials would generally be considered as unbiased.

SANFORD E. THOMPSON, M. AM. SOC. C. E. (by letter).—In this report the writer notices that "aggregate" is defined as "The mineral portion or the larger sized particles forming the body of a concrete or of a road surfacing," etc. Mr. Thompson.

This definition is at variance with the use of the term in connection with concrete construction, and as universally adopted in practice. It also disagrees with its use by the Special Committee on Concrete and Reinforced Concrete.

The generally adopted use of the term, "aggregate," is: the entire mineral inert material, such as sand, broken stone, etc., in a concrete or a pavement.

Any other definition is illogical and unscientific, because there is no well-defined line between fine and coarse aggregates, and, in certain cases, the coarse aggregate may be a material no coarser than a very coarse sand. Even in a bituminous mixture, there is no line of demarcation after the fine and coarse materials are in place in the pavement, the effect of the mixture being simply a graded mineral substance ranging from coarse to fine. The writer, therefore, offers the following as a substitution for the definition of aggregate:

Aggregate.—The mineral inert material, such as sand, gravel, and broken stone, with which the cement or the bituminous material is mixed to form a cement concrete or a bituminous concrete. Fine aggregate may be considered as the mineral inert material finer than ¼-in. mesh in size and coarse aggregate the material coarser than ¼-in.

PRÉVOST HUBBARD, ASSOC. AM. SOC. C. E. (by letter).—The following comments are made with some reluctance on the part of the writer because for a number of years he has been engaged in an attempt to standardize the nomenclature of bituminous materials through his connection with a sub-committee of six engineers and chemists Mr. Hubbard.

Mr. Hubbard.

of the American Society for Testing Materials appointed for that specific purpose. He fully realizes the difficulties attending any attempt to standardize nomenclature, and, therefore, he is more inclined to constructive work than to purely critical work. The satisfactory definition of a single term is at best no easy matter, and when a number of terms applying to the same general subject are to be defined, the complexities increase enormously. Every term then has to be considered in its possible relation to other terms which have already been defined, and it becomes necessary to make haste slowly in order to obtain results. Definitions of a few important terms may be put forward safely at one time for discussion and criticism, and after general acceptance, they may be used as a foundation on which to build a standard nomenclature. The preparation and submission of a large number of terms simultaneously, however, is apt to cause confusion in the minds of those who have not made a study of the subject, and result in their blind acceptance of definitions which, presented singly, would have called forth considerable discussion and criticism. Also, when the definition of a term has already been adopted by a technical society of recognized standing, it would seem unfortunate, from the standpoint of standardization, for another society to accept a different definition for that term without some very good reason.

These remarks apply to certain definitions put forward by a majority of the Special Committee. The writer, therefore, takes this opportunity to discuss them briefly, and, without injecting his personal views, show why some of them, at least, should not be accepted by the Society.

The recommended definition for "Bituminous Concrete Pavement" includes "Sheet Asphalt Pavement" as also defined. This conflicts with the definition for "Bituminous Concrete," as given under the recommended definition for "Concrete". In other words, as defined, a bituminous concrete pavement might be one composed only of sand and bituminous material incorporated together. "Bituminous Concrete", however, must, according to definition, consist of an intimate mixture of gravel, shell, slag, or stone particles with certain proportions of sand and bituminous material.

The recommended definition for "Foundation" is faulty if the definition for "Roadway" is accepted. Thus "Foundation" is defined as being "the portion of the roadway below and supporting the road crust." "Roadway," according to definition, is synonymous with "Carriageway," and "Carriageway" is defined as being "that portion of the road particularly devoted to the use of vehicles." "Road" is defined as "a highway outside of built-up districts". Therefore a foundation, according to definition, occurs only as a part of a highway outside of built-up districts.

Mr. Hubbard.

In like manner the recommended definition for "Pavement" is faulty, in so far as it applies to a structure for carrying vehicular traffic. According to definition, it is first of all "the wearing surface of the carriageway" or "portion of the road" which is "a highway outside of built-up districts". A pavement, therefore, can only occur outside of built-up districts, if the recommended definitions are accepted. If these definitions are accepted, we are thus forced to the conclusion that streets, which are defined as being highways in built-up districts, cannot be pavements, and that they have no foundations.

The recommended definition for "Filler" would appear to be incomplete, inasmuch as it does not include material used to fill joints in Portland cement concrete pavements, but only in brick or block pavements.

The definition for "Bituminous Cement", if broadly interpreted, would include practically all bituminous aggregates used in highway work. This is not consistent with the customary usage of the term.

The use of the word "asphaltic", in the recommended definition for "Cut-Back Products", is either meaningless or misleading. The definition recommended in 1913 to the American Society for Testing Materials by its Committee D-4 has not been improved by inserting this word. If asphaltic is intended to mean native asphalts, its significance is not clear, and if not, it is superfluous, as many petroleum residuums are asphaltic. The term "cut-back" first of all implies previous distillation, so that a native asphalt fluxed with a distillate could hardly be called a cut-back product.

The recommended definitions for "Oil-Gas Tars" and "Water-Gas Tars" are identical with those recommended in 1913 to the American Society for Testing Materials by its Committee D-4, except that the words "high temperatures" have been omitted. It would seem preferable to make use of this qualification, as oil vapors may be cracked under a great variety of conditions, but it is only at high temperatures that cracking produces oil-tars and water-gas tars.

The recommended definition for "Free Carbon" limits the occurrence of free carbon to tars only, whereas it may occur in any type of bitumen which has been subjected to excessively high temperatures. Moreover, it is defined as "matter which is insoluble in carbon disulphide". In certain tars, such as blast-furnace tars, mineral matter may be found to the extent of 5% or more. Under the definition, this would be considered as free carbon, which, of course, is wrong. The definition adopted by the American Society for Testing Materials for "Free Carbon in Tars" is to be preferred. This definition is as follows: "Free Carbon in Tars is organic matter which is insoluble in carbon disulphide".

Mr. Hubbard.

The recommended definition for "Fixed Carbon" differs from that adopted by the American Society for Testing Materials, for no apparently good reason, and is, in fact, incorrect. The word "coke," after residual, has been left out, and the words "highly heating" have been substituted for "burning". Thus the adjective "residual" has been made to take the place of a noun. If the word "coke" is eliminated, "residual" should be changed to "residue" or "residuum". Even if this were done, however, the definition would be incorrect, as the process indicated might be conducted on a bitumen without producing fixed carbon. It is quite possible to heat asphaltic hydro-carbon products highly in the absence of free oxygen without producing coke, in which case fixed carbon would not be produced. If, however, the material is burned in the process, coke is produced and also fixed carbon.

The recommended definition for "Flux", though correct as far as it goes, does not go far enough. For example, fluxes are limited to "fluid" and "semi-fluid bitumens", whereas they may be solid products. Thus naphthalene, a white, crystalline solid, may serve as a flux for hard tar-pitch, a combination of the two producing a soft or even fluid bitumen.

In view of the foregoing it is suggested that the proposed definitions be given very careful consideration with a view of possible modification before they are accepted by the Society.

This Society is not responsible for any statement made or opinion expressed in its publications.

DISCUSSION ON CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINEERS.*

By Messrs. Edgar Marburg, P. A. Beatty, H. E. Phelps, Ernest McCullough, M. J. Henoch, and Leonard Lundgren.

Edgar Marburg, M. Am. Soc. C. E. (by letter).—The writer has read this report with interest. Inasmuch as it is the intention of the Committee to follow this with a more complete report, the writer ventures to suggest the desirability of considering the preparation of two additional average yearly compensation curves, of which one would exclude the upper and lower 5% of the returns for each group, and the other the upper and lower 10% for each group. These curves would thus represent, respectively, the average compensation of the middle 90 and 80% of the membership of each group, and, as such, would serve as more reliable criteria as to what may be called the "average salary expectation curve," according to length of professional service, in so far, at least, as such expectations can be safely premised on experiences. Mr. Marburg.

To illustrate the misleading character of the present average yearly compensation curve, attention is called, for example, to the group of 69 members who have had 27 years of experience. In that group one particular individual happens to command the extraordinary professional income of $150 000 per annum. If that individual alone were excluded from this group, the average yearly compensation of that group would be reduced by more than $2 000. In the other group, in which a single income of $150 000 appears, there are 118 members, and despite this relatively large number, the exclusion of this one individual from that group would reduce the average yearly compensation of the entire group from $5 721 to less than $4 500.

*This is a discussion on the Report of the Special Committee to Investigate Conditions of Employment of, and Compensation of, Civil Engineers, presented to the Annual Meeting, January 21st, 1914.

Mr. Marburg.

The writer is strongly of the opinion, too, that the earnings of the 3 214 members who failed to respond to the circular inquiry are likely to be very much lower than those of the 3 636 respondents. The effect of the exclusion of this silent element on the returns reported by the Committee must necessarily remain a matter of conjecture, but, in the writer's judgment, it can hardly be doubted that its effect, if it could be determined, would be decidedly in the direction indicated. It is only human that an individual who realizes that he has been more or less of a failure, at least by the standard of earnings, would be reticent in his attitude toward an inquiry of this nature, notwithstanding assurances of secrecy.

The writer shares the opinion commonly held by members of the Engineering Profession, that, as a professional class, engineers are underpaid. In the broad consideration of that question, the average compensation curve is much more significant than either the maximum or minimum compensation curve. It seems especially important, therefore, that the average yearly compensation curve should also be constructed in the manner suggested, in order that the danger of drawing hasty and unfairly optimistic conclusions from the data collated by the Committee may be minimized; for even then, as has been pointed out, the showing would probably be much more favorable than is to be anticipated from complete returns from the membership of the Society, not to mention the large element—especially in the lower professional ranks—which is not identified with the Society.

Mr. Beatty.

P. A. BEATTY, M. AM. SOC. C. E. (by letter).—The writer would suggest that it might be useful to prepare an "average yearly compensation" line of those who receive $15 000 per annum or less from the practice of their profession.

The percentage of engineers who receive more than $15 000 annually is very small, the writer believes, and the elimination of those who receive more would lower the "average yearly compensation" line considerably. For example, take the twenty-seventh year. The average yearly income of 69 engineers is given as $8 023. Eliminating the $15 000 man, the average annual income of 68 engineers is reduced to $5 935.

To obtain an idea of, say, 85% of the Profession, which would probably be useful in an investigation of this kind, the elimination of exceptional incomes would give a line representing the earning capacity of the greater part of those engaged therein.

Mr. Pheips.

H. E. PHELPS, ASSOC. M. AM. SOC. C. E. (by letter).—This report is most interesting and valuable. However, it does not seem probable that the average yearly compensation curve, as determined by the Committee, correctly represents actual conditions. The fact that only 53% of the membership of the Society reported their compensation, is

doubtless due to a variety of causes, but it seems reasonable to believe that the main cause is an unwillingness to report a low compensation. Moreover, if the words "Civil Engineers" refer—as generally assumed—to all graduates of technical schools and all others with an equivalent education and training, and not only to members of the American Society of Civil Engineers, the compensation of these men should be ascertained, if possible, and incorporated with the information already found, in order to show the true state of affairs. Mr. Phelps.

It is doubtful if the well-nigh universal dissatisfaction of engineers with their income and general status would be so pronounced if the curve presented by the Committee showed the true state of affairs, low though it is. From the writer's acquaintance among engineers, he does not believe that their average yearly compensation is one-half, or, at most, two-thirds, of that shown. Doubtless, many engineering firms are represented therein by the large incomes of the members of such firms, and not at all by the small incomes of the draftsmen, transitmen, and assistant engineers employed by them. The members of this Society should not spend too much time contemplating the dizzy altitudes reached by the maximum compensation curve, but rather should study how to raise both the true minimum and average curves, which are much too close together and lower than they should be. The Society itself should take some action along this line, and the writer believes the most effective action would be, in some way, to assist engineers to obtain employment when they need it.

ERNEST MCCULLOUGH, M. AM. SOC. C. E. (by letter).—The writer has read this report with interest, and feels certain that it will be ably discussed by the editors of the leading technical journals. He hopes that these editorials may be offered by members of the Society and be printed in the *Proceedings* and *Transactions*, for he is sure that the opinions of the editors will be a reflection of those of many members. Mr. McCullough

The report is based on replies from about one-half the membership of this Society. The total number of engineers enrolled in the four national engineering societies—Civil, Electrical, Mechanical, and Mining—cannot be more than 20 000, when one takes into consideration the number of men enrolled as members in more than one of these societies, the total of the separate lists reaching to more than 27 000. These represent the men who have achieved some measure of success, yet many among them feel that Fate has not been kind. Of the 20 000 men, less than 4 000 have answered in such a manner that their replies could be incorporated in the report.

Statistics from engineering schools show that the number of such schools has increased greatly in the past 20 years, and that of the total number of men graduated from such schools, more than 60%

Mr. McCullough.

have been graduated since 1900, just 14 years ago. The first school of engineering was established in the United States in 1824, and the first man was graduated in 1826. The increase of interest in technical education, therefore, has exceeded the increase in population, but as engineering is a profession which is peculiarly the product of civilization, the increase, perhaps, is not disproportionate to the general world advance.

Numbers of men calling themselves engineers, some of whom attain high standing, are non-graduates, and many are engaged in engineering work who did not complete a four-year course in a technical school. That numbers go into the work after partly completing a course of study in engineering schools is well known, and many of these men are good engineers. The writer has been informed by a professor that on an average probably 20% of the freshmen complete the work of the senior class. The number of alumni of a school, when compared with the graduates, shows that this statement cannot be far wrong. In a certain college in the United States—not an engineering school, however—established in 1837, the number of graduates has been 15 000, yet the living alumni number 12 000, a majority being enrolled as members of the alumni association.

This being admitted as a state of affairs existing in engineering schools, the number of men practicing engineering in the United States must be several times the number enrolled in the national societies. It may be not far out of the way to state that the less than 4 000 men whose reports are tabulated and shown on the compensation chart issued by the Committee, is a very small percentage of those whose interest in the work of such a committee is lively.

In the writer's opinion, it is not so much the matter of compensation that the Committee should consider as the conditions of employment and the treatment of the men who have received enough training in engineering to lead them to follow it as a vocation. The custom is to engage them in a hurry in order to push work to completion, and rarely is a man given a week's notice of dismissal. The majority of men employing engineers and engineering assistants prefer to keep them in ignorance as to when their services will be no longer required, fearing that they will leave for a new job before their work is completed, thus placing the employers under the necessity of getting new men and thereby increasing the cost for engineering services. It is common with railways to pay their engineers from the 20th of the month up to the 1st, thus retaining two-thirds of a month's pay. Frequently, the men are dismissed on the 1st and their pay is not forwarded to them until the regular time, giving them no surplus on which to live until it comes or a new job is secured. It is not uncommon for men to be discharged after many years of faithful service, and be replaced by younger men at lower pay.

Mr. McCullough.

The seasonal employment of engineers, so far as this factor relates to their work, puts them on a plane with common labor. The pay being intermittent and the men being subject to the same troubles that all are subject to, such as illness in their families, injuries and illness to themselves, sporadic employment at pay which is seldom more than a bare living wage when employed, being below a living wage when the average is considered, causes much needless distress in a class of men whose training must be high and who are usually well educated. The work of the engineering societies should be directed toward securing better terms for all men who have received the necessary training.

Numerous companies make a good profit in securing employment for technically trained men. Their rates are very high, and they enforce collections mercilessly. Men are given positions—which these companies say will be permanent—only to lose them in a short time, often before the commission to the employment agency has been fully paid.

The Society should start some method, in connection with the other national societies, whereby employment may be obtained, a clearing house as it were, for the placing of jobless men in touch with jobs. Members of the societies should pledge themselves to employ only men recommended to them by this department. The Committee, further, should enlarge the scope of the inquiry to cover every man who has been graduated from an engineering school within the past twenty-five years. This would imply that the inquiry into conditions existing among engineers should be extended to all engineering graduates, and not to men who are not graduates. The men, however, who have achieved such a measure of success as to enable them to be enrolled in the American Society of Civil Engineers should be treated as a distinct class. The writer knows a very large number of men fully qualified to be members of this Society who do not join for the sole reason that their income is so precarious, and who are out of work so often, that they feel that it is impossible to ally themselves with the Society. These are the men who really impress employers with the fact that many things are not as they should be with the vocation of the engineer.

Mr. Henoch.

M. J. Henoch, M. Am. Soc. C. E. (by letter).—The writer is very much interested in this report. He realizes the great amount of time and labor required to collect, compile, and digest the mass of data requisite for the proper consideration of this important subject, and it may be, therefore, that the following remarks are premature. They are not offered, however, with any intent to criticize the excellent work of the Committee, but to bring out two points which appeal to the writer.

The first is in regard to the Committee's conclusion that the membership of the Society is large enough to be representative, and to be typical of the various stages of engineering life.

Mr. Henoch.

The members of this Committee are all eminent and successful engineers, live in an environment of "big things", and very naturally view conditions from a different standpoint from those who are not so successful. The writer has no means of knowing what percentage of those actually engaged in the practice of civil engineering in the United States are connected with this Society, but the proportion certainly is small.

The membership of the Society is chosen by a process of elimination which excludes the less successful engineers, and there are thousands who, although eligible to membership under the rules of the Society, are, nevertheless, unable or unwilling to afford the expense thereof, small as it may appear to their more prosperous brethren. There are many trained and capable engineers working for salaries of from $125 to $150 per month, who have families or dependent relatives to support, and to them the payment of $25 for entrance fees and $15 for annual dues looks like an unsurmountable obstacle. It may be said, therefore, that, as a rule, it is only the more successful engineers who become members of the American Society of Civil Engineers, that the membership is not large enough to be representative, and that it is not typical of the various stages of engineering life.

Also, in regard to the curve of average yearly compensation shown on the diagram presented by the Committee: it appears to the writer that this does not show the thing which appeals to the average engineer. It is true that it shows the average yearly compensation of the engineers reporting, but it does not show the yearly compensation of the average engineer. An inspection will show that this curve is unduly influenced by the curve of maximum compensation, and that every fluctuation of this maximum curve is reflected by a corresponding fluctuation in the average curve, but the minimum curve has, in general, no corresponding effect.

It will generally be admitted that the very high salaries reported are exceptional, and are by no means as frequent as the low salaries, yet their effect on the average curve, as compared with that of the low salaries, is (roughly speaking) inversely proportional to their relative frequency. For instance, the conditions shown for 18 years' experience is an exaggerated case, but serves well as an illustration. In this case the maximum salary is 114 times the minimum, though the average is only 4.3 times the minimum. Considering the extremes only, it requires 32.74 men at the minimum salary with 1 man at the maximum salary to produce the average shown; or, in other words, it requires practically 33 men at the minimum salary to offset the effect of 1 man at the maximum salary. The ratio of the minimum to the average is 1 to 4.33, though the ratio of the average to the maximum is 1 to 26.22.

Mr. Henoch.

It would appear, therefore, that the thing which really shows the conditions of the average engineer is (to use the terms of the Committee) the salary of the "middle-man" or that compensation which is exceeded by and which exceeds that of an equal number of men.

Mr. Lundgren

LEONARD LUNDGREN, ASSOC. M. AM. SOC. C. E. (by letter).—The writer has studied this report with interest.

The Committee states that the average curve shown in the report is, if anything, too low; that the general average of compensation of 3 636 members is $4 325; and that the average yearly compensation for 1 972 members whose experience is 15 years or less, is $2 827.

The writer feels that the impression will be created that the average engineer receives the average yearly compensation shown by the diagram accompanying the report. The initiated know that this is not the case, and that the majority of those answering the questions of the Society were the most successful engineers in the United States, which fact raised the average considerably. This point should have been emphasized in the report. If the curve was intended to show the ideal salary that the Committee thought an average engineer should be paid, it would be admirable.

It is known that the minimum wage of a technical graduate of one year's experience is $360 per year; that $720 per year is considered a good job; and that $1 200 per year is an exceptionally good position, and the writer can scarcely believe that an engineer would receive from any one the maximum salaries given in the report ($2 000 for one year's experience, and $5 000 for two), except for reasons outside of the realm of engineering.

The conditions after 20 years' experience can be analyzed similarly. The lowest wage known to the writer for this term of service is $900. An engineer is considered by his co-laborers as a success if he receives a salary of $3 000, and as very successful if he receives a salary of $5 000. The average shown by the diagram is $4 941, which is at least 50% higher than the salary of the average engineer of 20 years' experience.

The writer quite appreciates the position of the Committee as to lack of data, but he feels that it has overlooked numerous possible sources of information, such as the salary lists of the engineering branches of the United States Government, of the States and large cities, of the railroads, and of the large manufacturing corporations, many of which could have been secured by proper requests.

It was hoped that the Committee would secure sufficient information to produce a diagram, similar to that accompanying the report which, in addition to the minimum and maximum curves, would have a curve showing what salary an average engineer would secure for his working life. This it is felt has not been accomplished.

AMERICAN SOCIETY OF CIVIL ENGINEERS

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

ROAD CONSTRUCTION AND MAINTENANCE.
An Informal Discussion.*

BY MESSRS. WILLIS WHITED, WILLIAM H. CONNELL, E. W. JAMES, CHARLES J. BENNETT, A. W. DEAN, HENRY W. DURHAM, ROBERT A. MEEKER, PAUL D. SARGENT, W. W. CROSBY, P. E. GREEN, E. H. THOMES, S. WHINERY, MARK BROOKE, WILLIAM R. FARRINGTON, H. B. PULLAR, ARTHUR H. BLANCHARD, W. H. FULWEILER, AND JAMES H. STURDEVANT.

ENGINEERING ORGANIZATIONS FOR HIGHWAY WORK.

Mr. Whited.

WILLIS WHITED, M. AM. SOC. C. E. (by letter).—This subject is of vital importance, because incompetency, inefficiency, or dishonesty in the handling of highway work may cause a larger percentage of waste of funds than in almost any other class of work. However excellent the personnel of the organization may be, there will be much waste unless all parties work harmoniously, steadily, and efficiently toward the end in view. There is the further difficulty, that, if the organization is not reasonably harmonious, many of the best men will become disgusted and resign, which would make it doubly hard to secure others to take their places. The subject can perhaps best be studied by taking a concrete example, such as the Pennsylvania State Highway Department.

The Department was first organized by an Act of the Legislature in 1903. The Act, however, was amended from time to time until 1911, when an entirely new one was passed, known as the "Sproul Act", reorganizing the whole Department, so that its functions may now be divided into three classes.

(1) The Department, at the expense of the State, is to improve and maintain, as funds become available, about 8 800 miles of roads, mostly

* At meetings held January 23d and 24th, 1914. As much of this discussion as possible is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Whited.

main thoroughfares, set aside by the 1911 Legislature, to which the Legislature of 1913 added about 1 200 miles.

(2) The Department, under the law, is required to furnish to counties, townships, and boroughs, as funds become available, State aid for the improvement and maintenance of highways. The State pays one-half of the expense, the other half being borne equally by the county and township, or county and borough, as the case may be, the Department having entire charge of such road work.

(3) The Department, under a Legislative Act of 1913, has technical jurisdiction over all improvements on about 82 000 miles of road in addition to the 10 000 miles previously mentioned, and these roads are under the control of the Township Road Supervisors acting in their respective townships. The Department also has charge of the purchase of road-building machinery, exceeding a certain amount. Contracts pertaining to work of this class are not valid unless approved by the Department. The State bears one-third of the expense of such improvements. This places all public roads, outside of cities and boroughs, under the more or less complete control of the Department.

For handling such extensive enterprises, involving the expenditure of many millions of dollars annually, three methods may be suggested:

(1) The appointment of a commission consisting of three or more members, who shall formulate all general policies and appoint officers to carry them out;

(2) The appointment of a single head, with advisory council;

(3) The appointment of a single head, without advisory council, except such as he chooses to accept from his subordinates for special purposes, the Legislature itself determining the general policy of the Department.

The advantage of the first method is that the united knowledge and experience of the whole commission is available for the settlement of disputed points and questions of policy. The principal disadvantages are: first, the division of responsibility; second, it is apt to become a mere debating club, which seldom accomplishes much unless dominated by one man who, being an official, can with difficulty be prevented from abuse of power. A third disadvantage of this method is that a competent commission for such a purpose is usually composed of very busy men, who have many other interests, making it extremely difficult to get them together with sufficient regularity to settle questions with the promptitude necessary for the most effective prosecution of the work, particularly as their salaries are apt to be much less than the real value of their services.

The principal advantages of the second method are that the members of an advisory council usually have an adequate salary, and can be required to hold meetings regularly. On the other hand, being

subordinates, they will have little power, and will therefore take but little interest in the work. Mr. Whited.

The third method, in which all authority is vested in a single head, constitutes in reality a despotic rule, which is by far the most efficient provided the proper man can be placed in the position and prevented from any misfeasance of office. The superiority of this form is shown by the fact that all military organizations from time immemorial have been under the control of single heads having despotic power, except that in modern warfare civil authorities have the right to deprive him of his commission in case he should abuse his powers or show incompetency. In warfare, efficiency is of paramount importance. Almost all industrial and business concerns are under the control of single heads, but with powers subject to reasonable limitations. The Pennsylvania State Highway Department is placed under a single head, whose powers are limited by the ordinary laws of the Commonwealth and by the Act under which he is appointed, which designates the policy to be pursued by the Department.

All contracts are approved first by the Highway Commissioner and then by the Governor and Attorney General. All appointments to the higher positions are approved by the Governor. All expenditures are audited and approved by the Auditor General. Such checks as these should be sufficient to prevent the head of the Department from misusing his authority in making appointments and from the misappropriation of any funds.

Under the above-mentioned Act, the Commissioner is in absolute control of the administration of his Department, assisted by two Deputy Commissioners, also under his control.

The First Deputy Commissioner, in addition to assuming the duties of the Commissioner during his absence, is in charge of the Bureau of Township Highways, and also of the granting of permits for special uses of all public roads outside of municipalities.

The Second Deputy Commissioner, in addition to acting as an assistant to the Commissioner, has charge of the licensing of motor vehicles, and the enforcement of State laws relative to the use of such vehicles on State roads. He also has charge of the finances of the Department.

The Chief Engineer has immediate technical and executive control over the whole Department excepting the Automobile Division.

There is a clerical and auditing staff at headquarters, performing the duties usual with such positions.

There is an Engineer of Bridges, who has technical charge of all bridges and culverts.

There is a Superintendent of Signs, and a Superintendent of Asphalt Construction, whose duties need no description. There is also a Division of Tests, and a Division of Statistics, charged with the duty

Mr. Whited.

of obtaining data as to the traffic on all roads under the jurisdiction of the Department.

There are fourteen Assistant Engineers, who have technical and executive control over their respective Districts, but who act only in a technical capacity on township road work, and an additional Assistant Engineer acting as office assistant to the Chief Engineer.

The maintenance of State roads is in charge of a Maintenance Engineer, subordinate to the Chief Engineer, and in charge of fifty Superintendents, each of whom has charge of the maintenance of all roads in his respective district. These Superintendents, acting under the direction of the First Deputy Commissioner, also have immediate technical charge of township roads and bridges, and are required to approve all plans for road improvements to be carried out by the Township Supervisors, of whom there are about 6 500.

All bills are approved by the various heads under whose jurisdiction they have been incurred, and are then audited by the Department Auditor and the Auditor General of the State, thus rendering impossible any considerable misappropriation of funds. All payments on contracts must be approved by the Assistant Engineer, the Chief Engineer, the Department Auditor, the Commissioner, and the Auditor General of the Commonwealth.

All surveys and plans are made by the staffs of the Assistant Engineers, and checked by the Chief Draftsman and his staff, located at headquarters. They are then approved by the proper Assistant Engineer, the Chief Engineer, and the Commissioner. Plans for bridges and culverts are made and checked in the Bridge Division, and approved by the Engineer of Bridges and the Chief Engineer.

Thus it will be seen that all matters of importance are passed upon by at least two competent men, who are entirely familiar with the conditions surrounding each case.

All contracts are approved by at least three men, in addition to the Attorney General of the Commonwealth, and all payments on contracts are checked and approved by at least three men before finally being approved by the Auditor General.

All work done under contract is under the direct supervision of an Inspector on the work, who is thoroughly conversant with the details. Such work is approved by the Assistant Engineer and inspected generally from time to time by the Asphalt Superintendent and Engineer of Bridges, each acting in his respective capacity, and is also inspected by the Chief Engineer.

Thus a serious error in design or construction, or the loss of funds through misappropriation, ignorance, or criminal waste, is effectively prevented.

Furthermore, nearly all the work is done under the eye and at the expense of the public, of whom a very considerable number are more

or less familiar with road building, and who, by appeal to the press, the Courts, or public officials, could cut short any gross incompetence, negligence, or dishonesty of employee or official. Mr. Whited.

The Act provides that funds for the improvement and maintenance of all highways, other than Township Dirt Roads, shall be distributed as equably as possible throughout the sixty-six counties of the State, which effectively prevents the Commissioner from showing any undue partiality toward any particular portion of the State. Hence there is always one man who can be held responsible for results in carrying out the orders issued by higher authority, and, at the same time, in the decision of important questions, there is always one of competent knowledge to whom he can turn for advice.

All appointments to positions in the Department are made by the Commissioner, and are not subject to other approval, except in the case of a few of the higher positions, which are subject to the approval of the Governor.

It is important that the Commissioner be given much freedom in making these appointments, because, when men having considerable authority are scattered widely over the State, absolute loyalty to the "chief" is of the utmost importance, and can be obtained more effectively by personal appointment than by any system of civil service examination.

At the same time, as many of the positions require a high degree of executive ability, as well as technical skill and knowledge, it is important that the appointments be placed, as far as possible, beyond the reach of "political spoilsmen". For this purpose it has been decided that, in the future, as far as practicable, all the higher positions shall be filled by promotion, after careful examination into the candidate's technical knowledge and experience, as well as a careful inquiry into his previous record, in order to ascertain his executive ability, trustworthiness, resourcefulness, tact, and general ability, to get the best results out of all with whom he comes in contact, whether superiors, subordinates, equals, or strangers, these qualities, at least for the higher positions, being really more essential than a high degree of technical skill or knowledge.

It is needless to add that the Commissioner himself must be possessed of a high grade of technical skill, as well as great business and executive ability, in order to accomplish in the best manner the results expected of him by those to whom he is accountable.

WILLIAM H. CONNELL, ASSOC. M. AM. SOC. C. E. (by letter).—About two months ago a search for literature on "Municipal Highway Engineering Organizations" was made by the Library force of this Society. This search covered the past 5 years, and only one article dealing with this subject was found. Papers, however, have been written relating to the routine of existing highway organizations, and this has also Mr. Connell.

Mr. Connell.

been covered in some public works reports, including organization charts for highway departments, sometimes termed "street departments"; and it is apparent from some of these papers and reports that the officials in charge are making the best of the conditions under which they are operating, but that they are simply outlining and dealing with existing organizations, without comment or constructive criticism regarding the organization of a modern highway bureau. This being the case, it may be well to pause for a few moments and analyze some of the reasons for paying so little attention to the organization end of this important subject, which is second to no other municipal engineering division, from a business and engineering standpoint.

Highway engineering is not new, and considerable advance, resulting in improved pavements, has been made within the past 50 years, but this advance has been achieved by the efforts of a few engineers working under tremendous disadvantages, through lack of co-operation by the Engineering Profession and the fact that highway engineering has been considered seriously by engineers as a body only within the past few years. The highway work, in a large percentage of municipalities has been handled by all classes of officials from as many different walks of life (none of which gave them a claim to any qualification for the work), or by a city engineer who has busied himself with water, sewer, and bridge problems, the nature of which diverted his attention from highway work. The latter involves so much detail of an engineering nature that it is not apt to appeal to one who is wrapped up in the problems pertaining to other branches of the Profession. As a result, the highway work was allowed to drift along until the highway department was considered to be the property of the politician, and, still worse, only recently it has been used by some business administrations throughout the country to parcel out a few jobs to men probably deserving of some recognition; consequently, the highway bureau has been made to suffer through the appointment of men conspicuously unfit for the work. In this policy a great mistake has been made, as the highway bureau, in a large measure, is the principal show-case of the city government—the pavements representing the goods in the window—and it behooves any city or State administration, political or otherwise, to look to its highways, for the public is alive to the situation, and recent developments have proved that more people can be reached and satisfied through an engineering highway organization conducted on a high plane, than through any other branch of public work. An adequate organization, however, is essential, as a successful highway administration is dependent on conducting and controlling the work with the least friction. Ease of operation is the most important factor, and this can only be obtained through an organization commensurate with the demands on it.

Mr. Connell.

The political view of the highway department was expressed only recently by a leading political light of one of the largest cities in America, who stated that the highway inspectors in his city were all right because "they used to be truck drivers and consequently knew the streets pretty well." This statement was made in all seriousness, and to an engineer. It is small wonder, then, that many highway organizations reflect little credit on our municipalities. In fact, it is remarkable that the few engineers who have devoted their lives to this great work should have succeeded in producing so many good pavements, for in these there has been very little improvement, as far as the standard types are concerned, within the past few years, or since engineers in general have become interested in the subject.

Much has been said concerning municipal and State highway organizations by new and inexperienced officials, who, instead of employing experienced engineers to plan their organizations, attempt to do so themselves, and often write articles on the subject which only too frequently are misleading, as they are not based on good engineering judgment coupled with experience in management on a large scale, both of which are necessary in planning such organizations or writing on the subject. Of course, a man familiar with business organizations for controlling work can plan a highway or any other kind of organization, but not without the advice of one familiar with all the functions and work coming under the jurisdiction of the respective organizations. Therefore, if it becomes necessary to plan a highway organization, it is far better to have the services of an engineer versed in the principles of organization and familiar with the work. In other words, the most economical, the quickest, and the surest means of attaining the end in such an undertaking is to pick a man whose qualifications come nearest to fitting him for the work, and, in the case of highway work, select a highway engineer.

With reference to the organization itself, the writer will assume that he is dealing with a large city, and that necessary modifications should be made, depending on its size. In a small city, of course, it would not be practicable to have as many separate departments as in a large one, but the principles set forth can be followed in the handling of the work. Instead of discussing existing organizations, an attempt will be made to outline a proposed highway organization commensurate with present-day requirements. In this it is most important to determine what functions should come properly under the jurisdiction of a modern highway bureau and just where this jurisdiction should start. The first step, or the laying out of the highways, should come under the head of "city planning," which is becoming more and more a special branch of the Engineering Profession, and the work is of such a character and the field is so broad that obviously all municipal engineering departments will necessarily have to be more or less

Mr. Connell.

affiliated with the city planning division, and the head of this division might be termed the city engineer. Therefore, it will be assumed that the highway bureau, after the layout has been planned, will start with the design of all work pertaining to the highways, including parkways, park drives, and small highway bridges. The larger bridges should come under a bridge department, as bridge engineering is distinctly a special branch of the Profession. After the design, of course, all necessary engineering work relating to lines, grades, and inspection, from the grading to the finished pavement, should be under the jurisdiction of the highway bureau. Before leaving the subject of design—in view of the tendency of late in our municipalities to create a central bureau of design—it might be well to call attention to the fact that the engineers in charge of construction and maintenance of highways would necessarily become specialists in this line of work, and should control and be held responsible for the design as well as the construction and maintenance. This is simply the logical procedure which should be adopted in any such work. If, therefore, there is to be a central bureau of design—which may be very desirable—it should be under the city planning division, and the designing—as far as the construction of highways is concerned—should be supervised by the highway bureau.

The next thing to be considered is one which is becoming more serious every year, namely, sub-surface structures and encroachments, which include all underground conduits, pipe lines, vaults, etc., steps, street signs, stands, and every kind of encroachment beyond the building line. These matters, together with permits and licenses for automobiles, vehicles, etc., should be under the supervision of a branch of the highway bureau. With respect to conduits, pipe lines, etc., the only solution of the problem for the protection of the pavement, convenience of the public, and general traffic conditions, would appear to be pipe galleries; but, in large cities, which are already paved and built up, this would require an enormous outlay. This question should be considered seriously, however, in growing municipalities.

Having provided for the design, sub-surface structures, and engineering work, including inspection, the next subject is the surface of the street, and here the first thing to determine is just where the jurisdiction of this bureau should begin and end. Generally, in all municipalities, the city controls the highways from house line to house line, regardless of the division of expense for the footways, paving, repaving, etc., which varies in different cities. This is a big problem in itself, and will not be discussed at this time. Assuming, therefore, that the city has such control over the highways, encroachments, street signs, license fees for automobiles, vehicles, etc., naturally come under the jurisdiction of this bureau, and right here is a big

problem—as is also the case with sub-surface structures particularly relating to vaults—that has not been solved, namely, an equitable and just rental value to be levied by the city for all kinds of projections—underground or above the surface—beyond the house line, and license fees on all classes of automobiles, vehicles, etc. This, however, as in the case of the division of expense for footways, paving, repaving, etc., is too big a question to consider at this time. To continue with the highway organization, it will be assumed that the supervision, control, and enforcement of all the regulations governing these matters come under the jurisdiction of the bureau of highways. Mr. Connell.

The next, and probably the most important, matter to be considered in connection with the work rightfully coming under the jurisdiction of a modern highway bureau is a branch of municipal work which is closely related to highways and plays an important part in their maintenance, namely the cleaning of streets. This branch of engineering work—for it is distinctly engineering work, as the life of the pavements and roads depends to a considerable extent on the kind of cleaning they receive—has never, except in a few municipalities, been placed on an engineering basis, and in many cities this work comes under the jurisdiction of a separate department, which not only results in increased supervision and overhead charges in connection with the care of the highways, but an overlapping of jurisdiction with regard to the control. In a well-organized highway bureau, including street cleaning, the street patrol inspection can be and is taken over by the men supervising the street cleaning. This makes it unnecessary to have a separate street patrol inspection force, such as is employed in many highway bureaus. The street cleaning forces are constantly at work, covering every street in the city at frequent intervals, and, being supplied with a memorandum book or blanks for the purpose, can write down observations of the conditions of the streets as well as supervise the street cleaning work.

The tendency of the day is to standardize and control work in a manner which will not only conserve energy and do away with unnecessary duplication, as far as individual effort is concerned, but will concentrate forces so that operations can be carried on efficiently and economically along the line of least resistance, as ease of operation is one of the most important factors to be considered in planning any working organization, and no step would accomplish more in this direction than the combination of the street cleaning and highway bureaus. This would have the added advantage of placing this work more generally on an engineering basis, which would undoubtedly lead, not only to more sanitary methods of cleaning, but to methods which would be more apt to take into consideration the maintenance and care of the pavements themselves than is likely to be the case where the street cleaning is not under engineering supervision.

Mr. Connell.

In connection with the street cleaning work there is also the collection of ashes and rubbish and the collection and disposal of garbage. Although this work is not distinctly a highway matter, the collection and disposal of ashes, and rubbish particularly, is so much a factor of the problem of preventive street cleaning—in which the crusade against overloaded and leaky wagons, the throwing of papers, store sweepings, etc., into the streets, plays an important part—that it more properly belongs under the highway than any other municipal department. In a lesser degree, this is also the case with the collection and disposal of garbage. The writer, therefore, for the time being at least, or until a better solution of this problem is presented, will place both these matters under the jurisdiction of the highway bureau.

With reference to the division and subdivision of the work, assuming that all that comes under the jurisdiction of the bureau is distinctly highway work, the construction and maintenance and cleaning of streets should be under one chief engineer, with as many division and section engineers as the size of the city and the extent of the work requires. The clerical, including auditing, stenographic, and general office force, and the division of sub-surface structures and encroachments, including permits and licenses, should, through their respective heads, come under the chief engineer, as should also the division of contracts, specifications, and general office engineering. The work under these divisions should be delegated in a like manner, depending on the extent and nature of the undertakings over which the respective heads have control. Each of these subdivisions embraces so much detail, with the consequent opportunity for constructive criticism, that in the limited time assigned to this subject it would be folly to attempt to elaborate any one of them herein. Therefore only the main subdivisions and functions coming under the general principles set forth for a modern highway bureau have been taken up. The chart submitted herewith, Fig. 1, covers the organization outlined, and is intended for a city having a population of 1 500 000, and covering an area of about 130 sq. miles. The details will be left for future discussion, which must necessarily go on until modern highway engineering comes into its own.

Before closing, and in order that all may realize the magnitude of the work of highway bureaus in comparison with that of other engineering organizations, the writer calls attention, for example, to the extent of the undertaking of the Water Board of the City of New York in connection with the new water supply from the Catskill Mountains and vicinity. This work is said to be second only to the construction of the Panama Canal—the greatest piece of engineering work of the Twentieth Century. Now, no matter what may be the nature of the work requiring large expenditures, it is just as necessary to see that the money is spent judiciously and to the best advantage in one branch

Mr. Connell.

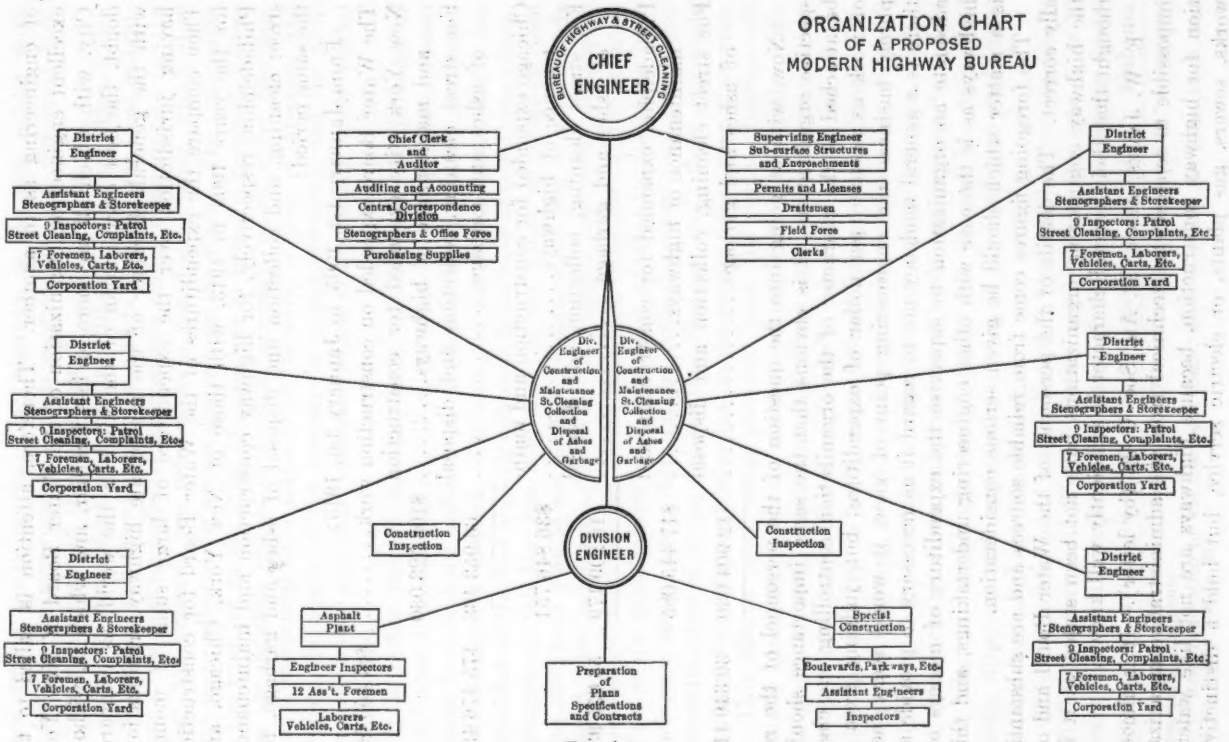

FIG. 1.

Mr. Connell. of engineering as in another. Therefore, attention is called to the excellent engineering organization of the Water Board of New York City, with which all are more or less familiar, and which is, without doubt, the best organization of the kind in the world, as compared with the general character of the inadequate highway organizations having jurisdiction over the expenditure of large sums of money. Then compare the expenditures of the Water Board for construction for the years 1905 to 1913, with those of New York, Chicago, and Philadelphia, respectively, for highway construction and maintenance, street cleaning, and collection and disposal of ashes and garbage, for the same period:

From January 1st, 1905, to January 1st, 1913:

The Water Board expended on construction work.....		$87 550 540
New York City expended for construction and maintenance of highways.....	$108 523 030	
For street cleaning, collection and disposal of ashes and garbage.....	66 953 463	175 476 493
Chicago expended for construction and maintenance of highways.....	$36 846 751	
For street cleaning, collection and disposal of ashes and garbage.....	16 209 179	53 055 930
Philadelphia expended for construction and maintenance of highways.....	$17 445 085	
For street cleaning, collection and disposal of ashes and garbage.....	12 904 030	30 349 115

Now, without going into the question of the personnel of the respective organizations, it is obvious that the same importance should be attached to the character of the organization controlling one class of work as another, per dollar of expenditure; but, judging from a purely business and engineering point of view, it would seem that there is a general tendency not to regard it as necessary to provide as adequate an organization to supervise the expenditure of moneys on highways as is the case with other engineering undertakings, and this is a matter which should be given serious consideration.

The foregoing figures come from reliable sources and are substantially correct. The details of the personnel of the Water Board and of the highway engineering organizations have not been stated as it is thought that their general character is sufficiently well known.

Mr. James. E. W. JAMES, ASSOC. M. AM. SOC. C. E. (by letter).—It is almost impossible to separate the technical from the administrative organization for highway construction, because highways are not like waterworks, sewers, gas plants, or electric service, but hold a distinctive

Mr. James.

place among public works. The highway is the first public work undertaken by government, and its construction and upkeep is both a duty and a right of the community.*

In many States the road taxes are still paid in labor. This, which of course is a poll tax—is always a road tax. Wherever local enlightenment has become sufficient to provide a money commutation for the labor, the proceeds are returnable to the district from which they have been collected for use exclusively on the roads. The origination of the road tax in the form of labor was in part the result of following the English system of local government, which alone was generally understood by a majority of the early settlers in America, and in part the result of the poverty in money resources and the richness in brawn and time resources which characterized newly settled communities.

It is rather strange that the labor tax has persisted in some of the States, but wherever it still exists, there is usually a local reason which is considered sufficient to explain adherence to so antiquated and inefficient a method. That the old law stands is no doubt due somewhat to the fact that though conditions have changed, the administration of the law has continued in the hands of unskilled men who have been able to see neither its defects nor any way to remedy them.† Its persistence, however, has caused one very pronounced condition of mind among the citizens of a large part of the country. Most men's grandfathers who lived west of the Appalachians built their own roads; later, their fathers built their own roads; and, consequently, they of to-day believe that they can build their own roads, and they leave the road labor tax on the statute books year after year.

This idea is much more prevalent than the casual observer will usually admit, but when we see that communities, in which the traffic has grown to such proportions and weight as to demand a much better type of construction than formerly, continue to depend on the labor tax and try to build roads without proper engineering, without proper financing, without even proper tools in some cases, we catch a glimpse of the inertia which characterizes a persistent idea. When the rural county citizen undertakes road work, he continues to believe that what his grandfather could do, he can do, and he, more than likely, dispenses with engineering advice, if the local good roads association does not force him to seek it.

This attitude of mind was embodied in the road laws of practically all the Southern and Western States until within the past 5 or 10 years, and is still reflected in many of them. The following States continue to collect all or part of the road tax in labor: Alabama,

*In elaboration of this idea, Dr. D. F. Wilcox, in "The American City," makes some interesting comments.

†"Road Legislation for the American State," by J. W. Jenks, Am. Econ. Assoc., Vol. IV, No. 3, May, 1889, p. 23.

Mr. James.

Tennessee, North Carolina, South Carolina, Georgia, Florida, Mississippi, Texas, Louisiana, North Dakota, New Mexico, Oklahoma, Arkansas, Montana, Kentucky, South Dakota, Colorado, Idaho, Illinois, Indiana, Minnesota, Nevada, Missouri, Pennsylvania, and Wisconsin.

Almost entire lack of engineering organization in connection with highway building in a large part of the United States has been the direct result of these conditions. Further, whatever efforts have been successful during the past few years in putting new statutes on the State books, none has succeeded in eliminating entirely the common idea that the farmer is as good a road builder as modern days can furnish.

The county and town system of road administration which obtains almost everywhere, places the construction and maintenance of roads in the hands of the county commissioners. In many cases, the commissioners have authority to divide the county into districts and appoint a supervisor over each district. Frequently, a penalty is prescribed for a man who, if appointed, refuses to act as supervisor. These men are furnished with a list of taxable polls in their several districts, and their duties include the collection of the road tax. They summon the road hands under the labor tax system, on the conditions fixed by law, and see that the legal time, or so much of it as may be required, is spent in working the roads. Those road hands who choose are usually permitted to pay out at a rate varying from 50 cents to $3 a day.* The supervisor collects the commutations, gives a receipt, and spends the proceeds on the roads in his district. His accounts usually stand like this:

Collected in road taxes	$787.50
Paid out for road work	787.50

Generally, a large part of the sum charged to road work goes, by tacit consent, as his perquisite, into the supervisor's pocket.

There has been a somewhat strong movement away from such conditions during the last 10 years, and we find many new laws drawn to relieve us of such ridiculous and wasteful methods of road administration. Still, the remedy has not been general, by any means, and there are some interesting clauses in the new laws. In the Alabama Road Law of April, 1911, for instance, the State Highway Engineer "may * * * be consulted by the county commissioners," and in cases where projects involving State-aid funds cost more than $3 000, "the highway engineer, with the consent and advice of the proper authorities in the county, may prepare plans and specifications" for executing the work by contract.

In the Arizona law of June, 1912, it is declared that "all roads and bridges, when constructed, shall thereafter be maintained and im-

*The common rate is $1 per day, but it ranges from 50 cents in South Carolina, to $3 in Nevada.

proved when necessary, * * * under the joint auspices and direction of the State Engineer and Board of Supervisors, * * *." Mr. James.

The Virginia laws of 1904, 1906, 1908, and 1910, are a respectable effort to do better things, but, from the limitations placed on the constituted road officials, it would seem that the General Assembly believed that the county commissioners knew more about road engineering than the State engineers whom they might employ under the law. Iowa has recently passed a new road law (April, 1913) which is a departure in legislation. It is the most systematic effort to correlate road work done at county expense that has yet been made. It could well be studied by the legislatures of three-fourths of the States. The new State of New Mexico goes one step farther in its road law of 1912. A State commission is created, and one of its duties is to appoint all county road commissions, each of which is composed of three members.

In general, however, except where State funds are involved, there is no engineering supervision required over county road work in the rural sections of most of our States. The counties thus conditioned spend, according to the most accurate reports attainable, about $61 000 000 annually on their roads. This is 40% of the annual road revenues of all counties.*

As soon as a State organizes a highway department and sets aside funds to aid the counties, the first systematic engineering organization is developed. The types of organization are simple and rather uniform for most States. They are confined to two common systems: one has a corps of assistant engineers reporting directly to the chief engineer; the other has a group of division engineers reporting directly to the chief. In a few cases, notably in Ohio and New York, there are deputies having general charge of a department of the work, as construction, bridges, maintenance. In these cases division engineers report to their respective deputies.

Under the division engineers there are resident engineers and inspectors assigned to projects.

A review of these actual conditions presents several questions well worth discussing. It is obvious that much of the reluctance on the part of poor counties to seek engineering advice is because there is no man available in the county, and an outsider—besides being an outsider, which frequently is considered more or less objectionable in itself—cannot be secured at a compensation warranted by the county revenues. As we see, therefore, it is not until the State steps in and gives the county funds that there is any engineering supervision of a large part of the county work. Cannot some simple engineering organization be created to deal with this situation?

Cf. Jenks, *supra*, p. 43. The principal exceptions are Massachusetts, New York, New Mexico, and Iowa.

Mr. James.

At a hearing of a legislative committee in a Southern State, the writer had an opportunity, about 2 years ago, to suggest a plan that he still believes has merit. The plan comprises a highway commissioner, paid by the State, drawn, if possible, from the staff of the State university or mechanical college, so that the additional salary would be small; a corps of division engineers assigned to groups made up of from eight to ten counties.

The commissioner would have general supervision of the division engineers, and they would have charge of all road work in the counties of their divisions. Many of these counties never would undertake macadam construction. Their roads, because of lack of local funds, must remain earth, sand-clay, or gravel for many years to come. The duties of the division engineers would be to supervise the expenditure of the county funds. The commonest needs in most rural counties are: the substitution of some material besides short-leaf pine for box culverts, the construction of adequate ditches, the proper crowning of the traveled way, direct and regular alignment, the intelligent mixing of sand and clay, the drainage of spring holes and swampy places, and the removal of vegetation from old mudholes. The division engineer's duty would be to see that suitable construction gangs are organized to work over the county and do their work properly. Labor taxes should be commuted by cash payments, and the money used to pay the road gangs. The old supervisors should be discontinued, and a group of foremen substituted, who, if possible, should be retained permanently, and trained in their work. When bridges or culverts are needed, the division engineer or commissioner can furnish plans, and the division man should see that the work is done in a correct and efficient way.*

This plan would much reduce the cost of engineering to the counties by a general sharing of expenses, and would be productive of good results in several directions. It would do away with the supervisor system, and would tend to remove the work from political influences. It would concentrate expenditures, and prevent the general custom under the ordinary county method of working every road in sight to please as many voters as possible, with the obvious result that the work is spread out so thin that the rainy or winter season destroys it all. It would create some standardization and begin the elimination of hopelessly ineffective methods used year in and year out by the county officials without apparent betterment of the roads. It would create in time some sentiment favorable to the employment of private engineers and a general raising of the standard of all public works. This latter circumstance would be a most happy result, for the need of adequate engineering in small municipalities through-

* Jenks, *supra*, p. 48.

out the South and West, and indeed almost everywhere in the country, is glaringly apparent on the most casual investigation. Mr. James.

When State funds are appropriated, conditions are at once produced that direct attention to another question. Shall the organization distinguish between construction and maintenance? The last report made by the New York State Commission recommended increasing the number of divisions and combining the responsibility for maintenance and construction. This recommendation was interesting and significant, coming from an organization which has had such a varied history as the New York State Commission. The State Legislature, acting in part on this recommendation, passed a law permitting an increase from six to not more than nine divisions, and otherwise embodying the recommendations. The type of commission was also changed, and a single responsible head provided. The present highway department in New York works under this new statute.

The labor organization and type of inspection required on construction, on one hand, and on maintenance, on the other, are so widely diverse that it appears to the writer that some separation of the two classes of work can be advantageously made. In the first place, if the division or district heads do not have to split their duties between the two classes of work, each can cover a larger territory. Further, if there is a system of standards used, the maintenance divisions can be enlarged beyond the size of those possible for construction divisions. This is so because, in any system so large as to demand division or district organization, the quantity of work makes construction by contract practically compulsory, and contract work requires constant and detailed inspection. On the other hand, maintenance by either the patrol or gang systems is force account or administration work, and as the patrolmen, foremen, and gangs are trained, they require less and less minute supervision. As a further consideration, it is not a bad plan by any means to establish as soon as possible the separate identity of the maintenance organization; because at last this will be the only one left, as in the case of the French *Routes Nationales* today. Trained engineers are generally required to take residences, whereas a division, when entirely under maintenance organization, would probably require no such resident engineers. In very large maintenance divisions assistants might be necessary to handle the larger re-surfacing projects, but in most cases trained foremen would be able to do a large part of the work under general orders.

On the other hand, an indisputable advantage comes from the vertical organization of divisions. If an engineer has entire charge of a restricted mileage during construction, he is doubtless the best prepared man obtainable to handle the maintenance of the same sections. He has watched the construction and knows the weak spots, the bad soil, the softer stone, and the doubtful drainage arrangements.

Mr. James. He knows the county thoroughly, and should have developed amiable relations with local officials and the citizens along the roads. All these matters would count much in a man's equipment for division work, but there is no insurmountable reason for a division man not leaving record maps sufficiently complete to inform a successor, instructed to take over roads for maintenance, in all the major and many of the minor conditions along the sections under observation. This matter of small-scale record maps is capable of large and valuable development. Further, a man detailed to maintenance, and concentrating his attention on it, should soon acquaint himself with the conditions in his division. It is seldom that labor used in construction stays to maintain, and, therefore, no especial advantages in the line of securing skilled laborers can be expected under either system. A new labor and supervisory organization will generally have to be created, and, in most instances, be recruited from the local supply.

Another matter that, from the standpoint of efficiency and economy, is of especial importance, is the place occupied under the State organization by the county road administration. Three States, New York, Iowa, and New Mexico, have statutes specifically placing the county road engineers or supervisors in the State system. There is no denying that this innovation (for, in the present condition of our State road laws, it can certainly be considered such) has little about it to be unfavorably criticized. Of course, when within a State the question of local autonomy comes up in any form, we always find some who oppose any restriction on home rule; but, if we analyze the basis of home rule, we find it chiefly concerned with matters of conduct. Now, road building is not a matter of conduct. Our fellow-citizen does not understand why his road money should not be economically expended by competent engineers. Now that two or three States have led the way, it may be hopefully expected that there will be a further move in the direction of placing some check on the indiscriminate expenditure of county funds under a local system which is worse than simply inefficient. This can be done, even when no State-aid feature enters in as a sop to the county. When such allotment does appear, there is no reason why supervision should not extend beyond the limits of the State-aid roads.

In Iowa the county engineers and the county officials, as far as road matters are concerned, are under the supervision of the State commission. In New Mexico the county road commissions are appointed by the State commissioner. In New York, county and town supervisors are under the division engineers, and in Illinois, the county engineers are appointed from a list of eligibles satisfactory to the State commission.

Just how far the State organization shall be indicated by law is a matter of debate. The writer believes that few States err on this point

Mr. James.

at the present time. Generally, except in three or four cases, the detail of the highway department organization is not carried beyond the State highway engineer under various titles. The details of organization are left to the administrative heads and the engineer. This is as it should be, until we find some organization that has details of particular merit capable of wide application. This freedom, however, does not preclude placing the county road authorities by law under the supervision of the State organization.

Many of the State departments to-day are advisory or nominally supervisory in their duties, and it is this restriction which, in spite of freedom in departmental organization, restrains their usefulness in so many cases to almost negligible limits. Where the great gain in efficient expenditure must come is in the county work, and the State engineer is helpless, however competent he may be, unless he is given some element of authority over the local activities. Merely advisory work is very often gratuitous. Some county officials consider it almost meddlesome. It is these local Solons that good organization must circumvent.

A review of the several State laws shows that the highway departments suffer from one very general condition. There are few single responsible heads. We are familiar enough with actual working conditions in some States to know that the work suffers, or has suffered, seriously because responsibility is not concentrated in one administrative official. It is very common to have the law stipulate that the engineer shall work in conjunction with an administrative official, sometimes even with an administrative body, of equal or greater authority. Arizona presents a case of this sort. In some States work is being done successfully, because, with a poorly devised law, a commission of three or five members has turned the work over to one of their number, or to a chief engineer, who acts practically as a single head. This has been conspicuously true in Virginia. The ill success of a many-headed commission can be seen in Rhode Island. There a commission of five members, one from each county, has had active charge of work, and instances have occurred where commissioners, visiting construction in progress, have changed the orders of the engineer in charge.

With regard to details of organization under the commission or responsible heads, the laws in most cases leave the highway department free to adopt such system as seems best fitted to accomplish the ends and purposes of the statutes. Were there a general system of single responsible heads, many States under their present laws, could develop thoroughly efficient organizations. The responsibility for the organization would lie with the head, and he would generally be unrestricted. There are thirty-eight States which have some form of highway department, but it is doubtful if more than fifteen of them

Mr. James.

ean develop efficient highway organizations, because of the divided authority and responsibility residing in several heads.

Mr. Bennett.

CHARLES J. BENNETT, M. AM. SOC. C. E.—With one or two exceptions, the speaker is impressed with the general soundness of the arguments presented by Mr. Connell. In the first place the formation of a standard organization for a highway department in a city is not entirely feasible. There are so many difficulties in the way of standardizing any particular department of a city that it would be impractical to consider any more than general principles to be used in all cities, instead of trying to standardize a system for one department in all.

For instance, a standard system applicable to New York City, Chicago, or Boston would certainly not apply to a smaller place, on account, not only of the size of the city itself, but the general geography, characteristics of the people, and the system of government. It seems plain, therefore, that if a standard system is to be devised, all cities in the United States should be classified and a system of organization for all departments formed, so that the entire operation of city government could be along standard lines for different types of cities.

This seems to be an ideal which cannot be reached, and the problem, therefore, must be to apply general principles to engineering organizations which shall tend to improve conditions which are bad at present. These applications should also furnish engineers with information which can be classified by engineering societies, so that costs and systems may be contrasted and certain valuable improvements in results gained.

There is no question of the need of an engineer to supervise not only highway departments, but all public works of any character. Therefore, a Municipal Highway Engineering Bureau should be a part, and a very large part, of an Engineering Bureau of Public Works, and public works of all kinds should be under the supervision of a trained engineer.

This principle, if applied to cities, will work with incalculable benefit, both in the improvement of the construction of public works and in their economical operation after completion. Granting this, therefore, Mr. Connell's statement as to the need of an engineer to supervise all highway work is evident, and the supervision of this work, as he states, should include, not only the actual construction and operation of these public works, but also the design of the different structures as well as the outline of the general plan to be carried out in the expansion of the city.

Now, a word as to the qualifications of an engineer in public service, and the difficulties of securing one who is competent to follow up work of this class: Engineers by training should be fitted to do all things necessary for the operation of such a magnificent department

Mr. Bennett

as has been conceived in control of the public work of a city or State. That means that the engineer must be not only a technical man but a business man who can see both the scientific and financial sides of the problem, and determine the advisability of spending any given sum of money for a certain purpose.

The second qualification means that the engineer must take a broader view of public work than he generally does.

In considering the operation of any city or State engineering department (and the ideas here outlined apply, it seems, particularly to the highway department), there is need of a better training for engineers in keeping accounts and supervising routine office work. The success of any highway bureau, or any other bureau which is under the supervision of an engineer, depends on its accounting system as much as on any part of the whole situation. The expenditures must be kept within appropriations, and work must be planned and executed in such a manner as to gain the full benefit, so far as possible, from the expenditure of moneys allowed. Therefore, the engineer should be trained, and highly trained, along business as well as technical lines. The natural tendency would be for an engineer to be too much given to minutiæ and complicated methods. The endeavor should be to devise a system of accounts as simple and free from unnecessary complications as possible.

This discussion has followed general lines more than the particular ones specified in the topic, but these ideas—which must be considered as general, rather than specific—can be applied to a highway engineering organization.

In connection with the discussion on highway work, both municipal and State, it is interesting to note the diversity of opinion among engineers as to the value of the work done. Within the past year a prominent engineer has told the writer that there are very few engineering problems to be faced in highway work; that this work is of the simplest nature, and, by inference, almost any one could become a highway engineer.

To the ordinary man's mind, the highest type of engineering would be that which would do, in the best manner, both the simple and the complicated things.

There are comparatively few very large structures or projects to be carried out by engineers, but, as indicated by Mr. Connell, the largest amount of money spent in engineering work is for the operation of municipal and State highway departments, and the results of this work are open to critical observation by all who are in possession of five senses.

Although the engineering problems may be simple, the problem of spending public money in an economical manner, is, by far, the hardest one which the engineer has to solve, and if this can be solved

Mr. Bennett. by improved business methods, as well as improved technical methods, it seems that we will have done some of the highest class of engineering work.

In conclusion, the speaker endorses Mr. Connell's statement, that the highway or other departments of cities or States should be freed from political influence, and that the spoils system should be entirely eliminated in the operation of these departments. Only a moderate amount of success can be attained when any system of politics, whether it be good or bad, is allowed to interfere with a municipal or State department, and when these departments are entirely free from political interference, then, and then only, will ultimate success be gained.

Mr. Dean. A. W. Dean, M. Am. Soc. C. E.—Very recently the word "efficiency" has become a particular favorite, not only with those who are directly concerned with State and municipal affairs, but with all who are interested in the administration and execution of public works. Witness the large number of governing bodies which have created commissions or boards of efficiency and economy to analyze and criticize the acts of public officials, and, by their advice, minimize waste and extravagance in the expenditure of public funds.

No department in State or municipality lends a greater field of action to such a board than the highway department, when competency is not the prime requisite in the selection of heads and assistants; and, on the other hand, no highway department consisting of competent men selected for their particular fitness for the positions they occupy will furnish a fair-minded efficiency board with any cause for reprimand or public criticism.

The preceding statements are made only to emphasize the fact that no highway organization can be successful unless competency is the first and only consideration in the selection, not only of the head, but of the entire body of the organization. Competency and efficiency are inseparable terms, for without one the other cannot exist.

A detailed description, either in words or graphically, of an organization adaptive to any and all conditions is obviously impossible. Highway laws in the several States vary widely, as do also conditions to be met in municipalities of varying wealth and population.

Supported by laws prescribing a well-defined policy in the expenditure of State funds, a single responsible head is preferable to a body of three or more; and, on the other hand, if the State has not, by legislation, fixed a general policy, a body of three may rightly be considered preferable. With or without a prescribed policy, a single responsible head with an advisory council having limited powers should prove efficient in carrying out large or small undertakings.

In a municipality it has been well demonstrated that a single responsible head is sufficient.

No organization can be long successful unless it is arranged below the head in military order. If the organization is small, the head may act as the chief executive; if large, there must be one chief executive charged with carrying out the general policies and orders of the head, as a division of responsibility at this point tends toward duplication, uncertainty, and consequent inefficiency. Mr. Dean.

Divisions and sub-divisions below the chief executive officer are dependent on the scope of the work to be done; in State highway organizations a suitable number of division engineers are charged with responsibility for both construction and maintenance in their several divisions. In municipal organizations each division should include the entire municipality, with a division engineer in charge of each branch of the work, that is, one in charge of bridges, one for street construction, one for maintenance, etc. For large undertakings the division may be subdivided into districts, with district engineers in charge responsible to the division engineers.

To summarize and further present the matter briefly, the following outline of highway organization is submitted:

1.—A single commissioner, or three commissioners, as quite definitely recommended above;
2.—A single responsible chief executive officer;
3.—As many divisions as may be necessary, each under a division engineer;
4.—Sub-divisions or districts, each in charge of a district engineer;
5.—Minor assistants.

All appointments should be governed entirely by fitness; there should be no changes in the personnel, except for proper cause; there must be no division of responsibility; all orders must be transmitted as in military practice.

HENRY W. DURHAM, M. AM. SOC. C. E.—It is of interest to have confirmed by Mr. Connell's search, the fact, apparent to all who have been charged with city street maintenance and repairs, that there exists little constructive criticism based on broad lines as to the methods of carrying on such work. Destructive criticism abounds. Mr. Durham.

Reports of citizens' committees denouncing indiscriminately pavements of bygone days, or the non-use of some special, possibly patented, cure-all street surface, the promoter of which has had an accelerator at work, illustrated by views of the depression where the prominent citizen's automobile was bumped, and accompanied by half-baked legal recommendations based on the American citizen's ineradicable impression that the millennium can be attained by "passing a law"—these, and the annual reports telling what has been done with the tools we have at hand, and the textbooks that tell much about good

Mr. Durham.

pavements, but little as to paving organizations, comprise most of our highway literature.

There have been, it is true, studies made and plans advocated by efficiency experts for the better handling of the routine work of existing highway departments, or for their improvement in details, but the results of Mr. Connell's investigations would seem to indicate that little has been written on the fundamentals of organization and the proper scope required of the department in charge of highways in a great city. This is possibly due to the fact that in America the demand for improved street surfaces, caused by the increase in number, weight, and speed of vehicles using the highways, is coincident with the arrival of conditions causing their upheaval to a maximum degree. In no other part of the world at the present time, and in no previous period of the history of the United States, has there been anything paralleling the amount of rebuilding and shifting of what were supposed to be established trade and social centers, that is to-day going on in all large municipalities.

While the general public is demanding the construction of streets with absolutely smooth surfaces for availability for motor race-tracks, that shall be unyielding and without surface wear, so as to endure for all time, constructed over subways and pipe galleries to avoid all future surface disturbances, it is at the same time abandoning whole districts devoted to residences and light traffic, and filling them with tall office buildings which, when the expected office occupants fail to materialize, are turned into factories having a population in some sections of New York larger than the great mill towns of New England; and is demanding that these buildings have adequate service for telephone, electric light and power, and water supply, including high pressure for fire protection; and, finally is planning new lines of subways to carry away the surplus population brought to these districts, and to open up new possibilities of change. To harmonize these conflicting demands would appear to be an impossibility. It is under such conditions that officials charged with the maintenance of municipal highways are to-day carrying on their tasks.

To construct and maintain pavements under present-day traffic is an occupation in itself. When to that is added the fact that in no great city can the highway officials determine with certainty whether the pavement laid to-day will be suitable for the traffic to be found using it 5 years hence, it will be seen that they are entitled to the benefit of the best constructive criticism available, and that the fault-finder, who devotes what knowledge he may possess to enlarging his own newspaper reputation by the cheap method of criticizing obvious defects, is actually blocking progress.

Mr. Connell has taken up the problem in the right way, and has indicated an outline for the commencement of efficient highway or-

ganization. It may be of interest to have the subject also treated from other standpoints. In the course of an investigation of municipal highway work in European cities, made during the past year, some points were noted as to their methods of solving this problem. Mr. Durham.

Two general methods are followed in different parts of Europe:

1.—A strongly centralized authority under which the entire city is sub-divided into a number of smaller unit organizations, each within its district having charge of all municipal work, closely governed by the central office;

2.—Local control where, in the city as a whole or as sub-divided in each of a number of independent units, a single head has control of all city work, with sub-divisions, each separated and independently charged with a single class of work.

The first system is best exemplified in Paris. In the organization of the street service and for all construction work in the highways, it is divided into seven sections, each headed by a resident engineer who has control, not only of paving work but of the laying of water pipes, sewers, and the supervision of any sub-surface work of private corporations. At the head of the bureau of street service is an Inspector General with necessary deputies and office organization, having under him several chief engineers, one in charge of public streets and street lights to whom the resident engineers primarily report; another at the head of the work of street cleaning; one in charge of gas and electric light mains; the fourth in charge of water and sewers.

Each chief engineer has the necessary office force, and several resident engineers are under his orders for special work and for the management and maintenance of work outside the city; but, within the city, all construction work on the streets is under the direction of the street service engineer in charge of each district. Each in his own section takes care of the paving work; lays water pipes; builds sewers; and supervises duly authorized construction on the part of gas and electric companies, so that no pavement can be torn up except by his orders or with his permission.

In London, on the other hand, the control is almost entirely decentralized. There each of the thirty different boroughs has its own city engineer or surveyor responsible only to the Borough Council for orders and directly in charge of all street paving, repairs, cleaning, and lighting. The works of general utility to the entire city, such as water supply, main-drainage sewers, and municipal tramways, are controlled by special boards independently of the boroughs, and do any necessary street work under the supervision of the local borough authorities. Smaller English cities have usually a city engineer, charged with control over all the city works, having under him a Department of Highways headed by a road surveyor, and an organization

Mr. Durham.

of assistants whose duties are confined to the maintenance, repair, and cleaning of highways. With some modifications, the system in the German cities is very similar.

In the first of the two systems there is one responsible head over all classes of work carried on in each unit—the unit being some convenient sub-division of the entire city—and though the different divisions of city work are each under special organizations, the actual execution, in theory at least, is controlled so as to render lack of co-operation or interference of different classes of work impossible.

In the second system, in the city as a whole, or in each of its independent units, in the case of large cities, there is centralized control to the extent that all construction, with the exception of water-works, is under the direction of a city engineer, but the special varieties of street work are usually carried on by independent sub-units. Of course, many exceptions are found in any necessarily brief and general classification like this. For thoroughness and theoretically perfect, systematic, and orderly procedure, the French method of organization seems to leave nothing to be desired.

The city work of London, on the contrary, is carried on under what is probably the most illogical and unsystematic arrangement that could be devised, but, judged by practical results, London presents probably the best appearance of any city in the world, as far as the streets are concerned, and Paris is constantly in a torn up and poorly maintained condition.

In Berlin, a city about equal in size to Paris, but divided into a number of independent city or borough governments, without a central control, but very thoroughly organized as units, the results show good conditions in some districts and poor in others. The practical deduction to be drawn from the comparison of these methods, not on paper but as worked out in the three great European cities, is that no system will produce results automatically, and that good results can be produced under adverse methods by a people accustomed to orderly procedure.

It will be seen that the scope of a department in charge of public highways can be very broad or very much restricted and still be in accordance with good practice in some prominent city.

Mr. Connell's plan seems to follow the French system, but without going far enough for completeness. If the work of the street department includes cleaning, it may well go farther and take in sewer, lighting, water and other city works requiring the use of the streets. If we believe, like Sterne, that "They order this matter better in France," we may well consider that a model city works department should be based on that of Paris, which, after co-ordinating all possible interests, furnishes ample opportunity for the card-index and loose-leaf expert to devise interlocking systems to his heart's content

until he arrives at his Utopia, where the Inspector Generalissimo, by a system of push-buttons at his desk, can run his department and never see the work. Mr. Durham.

The weak points which make this system difficult of application lie in the question of personnel. We have in the United States no trained class of public works officials, no body of Government engineers organized like the French Corps of Bridges and Highways, and we have frequent elections and still believe at heart that "to the victor belong the spoils" including the right of spoiling the work done for us by the vanquished. It is hard enough to find one civil service man to fill a responsible position; to find seven equal and uniform would be almost impossible. In the light of possible conditions, it would seem to be a better policy to concentrate along all classes of work, organizing the Bureau of Highways into sections for doing specific things in charge of the men best qualified to do them. An outline of such an organization, based on experience in Manhattan Borough, but making improvements in some existing conditions, is somewhat as follows:

The head of the Bureau of Highways has charge of all construction and maintenance work on street surfaces between building lines, and issues and controls permits for necessary street openings of whatever nature, under the direction of a Commissioner of Public Works whose authority includes, besides highway construction, the sewers and other sub-divisions and in whose office all financial matters, including auditing, contracts, etc., are taken care of.

To avoid duplication of work, a single Bureau of Design and Survey carries on all necessary work for the different construction bureaus in the department, its work for each, however, being under the direction of the head of that bureau. This applies, not only to the making of preliminary and contract plans, but to the furnishing of parties for surveys, giving grades, and making measurements for final estimates.

Under a Chief Clerk is the control of all correspondence and records of the bureau, including the necessary organization for filing, recording, and handling data for the maintenance of a live record as to street conditions, necessary repairs, etc.

As has been pointed out, the control of street openings is an essential preliminary to the work of any highway department. No system, however complete, will be of more value than as a historical record unless some plan lies back of the causes necessitating such openings. It will be essential ultimately that our great cities realize the desirability of the adoption of a systematic plan for sub-surface structures for new districts and take up the problem of an orderly re-arrangement of these structures in the most congested sections. Thus far, charter rights of individual companies and the unwilling-

Mr. Durham.

ness of various departments to co-operate with one another have rendered futile any attempts in this direction, resulting in a tangled mass of sub-surface structures in our central districts, with locations frequently unrecorded, and the repair or extension of which requires an undue amount of street surface disturbance. Pipe galleries under all streets are a dream of the idealist, but an orderly planning which shall place under footways the lighter house-service lines, leaving the large mains under the roadway at regulated intervals, and shall do away with unnecessary duplication of facilities in any one street, and a limited provision for pipe galleries in the most crowded sections, is not impossible of attainment. It will require, undoubtedly, amendments to the charter, both of municipalities and corporations, and the vesting of the right to order changes in the body controlling the city policy. With such a condition existing, the permit office of the Bureau of Highways will have actual and not merely (as at present) nominal control over all street openings. This can be done without interfering with the rights of any other department or corporation to get at their structures for emergency repairs. The usual procedure will involve application to the permit office in advance of making any opening in the pavement, and a deposit of sufficient money to cover the cost of restoration, inspection of sub-surface work, back-filling, and subsequent repair and maintenance.

After street openings are properly controlled, the making of repairs necessitated by ordinary wear is of next importance. For convenience, this work has been placed in two divisions: one having charge of all repairs to block pavement, including stone block, wood and asphalt blocks, a large part of which work can be done by gangs with a limited quantity of new material, and repairs to sheet-asphalt pavements, which require the use of an asphalt plant, either owned by the city or operated by contractors. To lay out the work of these divisions properly, a system of street inspection is essential, and this is done by a division of patrol inspectors, each having a definite district and making daily reports of all defects, which are immediately plotted on an office map from which the day's work for the gangs can be laid out to the best advantage. Another division looks after all matters pertaining to sidewalks, whether carried on by the city or the property owners, and has control of such other matters as street signs, removal of incumbrances, etc.

Finally, as the perfect non-wearing pavement has not, as yet, been discovered, it becomes necessary to provide for renewals of street surfaces from time to time. This, for the present at least, is best done by contracts, under the supervision of a division engineer with a necessary organization of assistant engineers and inspectors.

Whether the street work is performed by city forces or by contractors, the purchase of new materials and their conformity to specifi-

Mr. Durham.

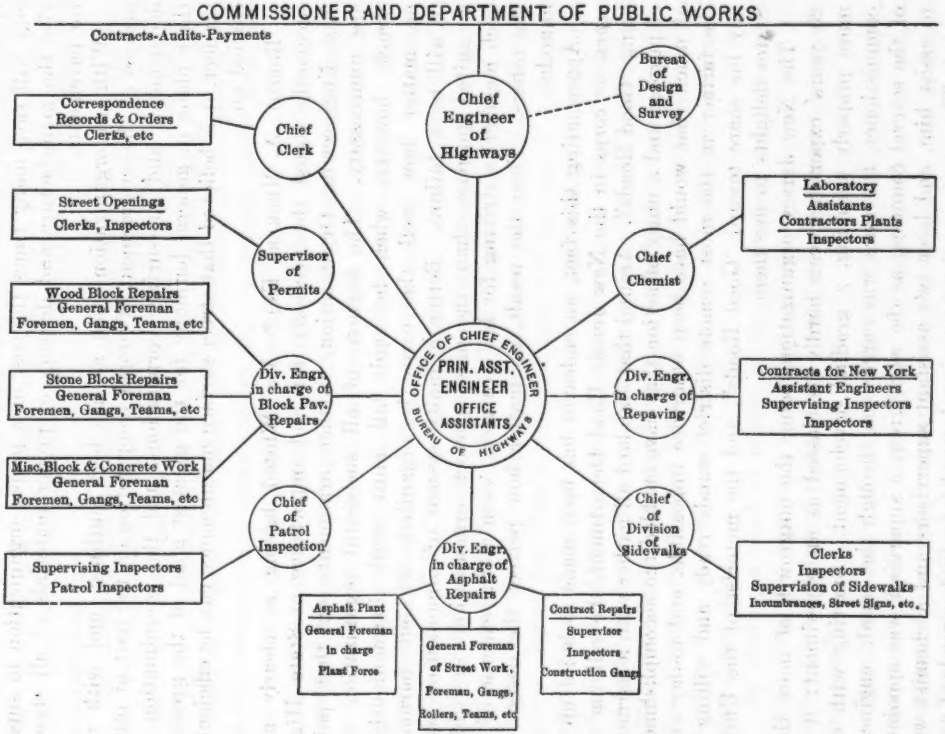

FIG. 2.

Mr. Durham. cation requirements is essential. Hence, one of the most necessary divisions is the laboratory and plant inspection force in charge of the chief chemist. Losses due to mistakes or inadequate inspection in this division may amount to many times in value what would occur from omissions or carelessness of inspection on construction, and the city will save many times the cost of a proper organization to supervise the manufacture and delivery of proper materials of all classes for pavements.

With an organization such as has been outlined, and with the proviso of the enforcement of proper co-operation on the part of other departments and sub-surface corporations, and the co-ordination of their plans in general harmony for the greatest good of the greatest number, it is believed that street surface maintenance can be efficiently carried on.

Mr. Meeker. ROBERT A. MEEKER, ESQ.*—Mr. Whited having so clearly and succinctly stated the necessity for and importance of State Highway Engineering Organization, further arguments on that point are unnecessary. The keynote of all successful organization was struck, however, when he said "all must work harmoniously"; no matter how well the corps is organized, without harmony it will be a failure. Better a faulty system of organization with a united purpose than the most perfect organization in which each member is striving for his own glory, even at the expense of all the others. Then the result, no matter how perfect the design, is anarchy.

Appreciating this fact, an endeavor has been made to build up an *esprit de corps* in the New Jersey Road Department, the rallying cry being "Good Roads". Around that standard all gather with a harmony of purpose and a unity of action that have enabled the accomplishment of much that would have been otherwise impossible, and to-day even the farmer in the most remote district stands ready and willing to pay his share toward "Good Roads", and the motorist of the United States delights to use them.

The New Jersey organization, being the outgrowth of more than 20 years' experience, can hardly be classed as an experiment; it is, more properly speaking, a gradual development. Starting with one commissioner, the work was carried on through the county engineers of the several counties; as the work grew, a supervisor was appointed to assist him, and later two assistant supervisors and a chemist were added. Then, owing to the increasing demand for a higher grade of road, caused by the advent of the automobile, a larger organization was demanded, and the re-organization under the present Commissioner was the result. It consists of the Commissioner, who is chief executive, the

* State Highway Engineer of New Jersey.

Highway Engineer, who must pass on the design of all engineering work, four Division Engineers, three of whom have each charge of a prescribed district and the fourth has charge of the bridges, a Chemist, who tests all road materials, twenty-one county engineers, who, though employees of the county, are also resident State engineers in their several counties, ten inspectors, and six foremen; the latter are to form the nucleus of a force that will be needed when the State highway system becomes an accomplished fact. Mr. Meeker.

The foremen and inspectors report in writing weekly to the Division Engineers, who in turn report to the Highway Engineer and he reports to the Commissioner, thus each has his alloted task and each his share of responsibility. The county engineers might properly be classed as brigade commanders having command of the work in their several counties and being subject only to general orders from headquarters as to standards that must be met.

The State highway system, just referred to, is also a natural outgrowth of the work, its aim being to unite the several county seats and to extend the main highways to the borders of the State. This being such a large proposition, it was deemed wise to establish a Highway Commission which should determine the general plan and location of the work. This Commission consists of the Governor, the President of the Senate, the Speaker of the House, the State Treasurer, and the Commissioner of Public Roads. This Commission has laid out a system of roads 1 500 miles in length, most of which are already improved, hence the State's principal task will be one of maintenance, which, owing to the fact that New Jersey lies between the two largest cities on the Atlantic seaboard, will always be a big one. Owing to the fact that many of our main highways have been laid out for from 100 to 200 years, their exact location is often hard to determine, hence it was necessary to add a right-of-way engineer to the force, and his services have proven so valuable that, in all probability, others will have to be added.

In closing, a word of tribute to the contractors should be added, for to them the engineers owe much; it is their practical skill that makes the designs and plans of the most perfect engineering organization possible.

PAUL D. SARGENT, M. AM. SOC. C. E.—The one argument that has been most effective in every State in bringing about the creation of a State highway department has been incompetency and inefficiency on the part of local officials in securing economical results in the expenditure of highway funds. Consequently, every State highway engineering organization, to prove its right to exist, must be developed along the lines of efficiency, competency, and honesty. Politics, in the ordinarily accepted sense of the term, can have no place in such an organization. Mr. Sargent.

Mr. Sargent.

It seems to the speaker that the best results will be obtained and there will be more general satisfaction when the work is in charge of a commission of three members, provided they are men of sufficient breadth of view to understand their problem in its largest sense.

The commission should formulate the general policy to be adopted by the department, unless this has already been covered by law, and should pass on all large questions of a business nature.

Unless the commission is in daily session, which is rarely the case, it will be necessary for it to select an executive officer, who will usually be the chief engineer.

Besides engineering ability, this man should possess a good degree of tact, for meeting and dealing with the public, especially local officials. This is particularly desirable where highway improvements are paid for jointly by localities and the State for this always means that the State directs the work, and, unless handled just right, local officials will feel that their authority is usurped. Other things being equal, tact in dealing with local situations should be a controlling factor in selecting subordinates all through the department.

The chief engineer should have absolute control of the appointment of all subordinates, and, of course, they should report to him. The size of the organization will depend entirely on local conditions, that is to say, the quantity of work to be done in a given time and the area over which the work is distributed.

The following organization seems to the speaker to be about as small as can be expected to handle efficiently any considerable quantity of work: A division of surveys and plans; a division of design and construction; and a division of maintenance.

The division of surveys and plans will make all surveys and secure all preliminary data necessary for a proper design of contemplated improvements. This division should furnish plans of the road as it now is to the division of design and construction, where, after examining the locus, with plans, profiles, and sections in hand, changes of alignment and grade and details of construction will be determined.

The plans will then go back to the division of surveys and plans for completion, including preliminary computations of quantities, on which an estimate of cost will be prepared and bids will be invited.

At the same time the division of design and construction will prepare specifications, advertisements for bids, contracts, etc.

After the award is made and work is in progress, the supervision and inspection will be done by the division of design and construction.

It can be readily seen that in a small organization one man might handle both of these divisions, as their work is intimately correlated.

The division of maintenance, as the name implies, will look after this work especially, and it is suggested here, entirely on the supposi-

tion that both the other divisions are fully occupied with their particular problems. Mr. Sargent.

This whole scheme is based on the supposition that there will be no division offices, as there are in several State organizations, but that all engineering work is done at department headquarters.

To complete the organization, there should be a division of tests and one of accounting. Tests should by all means be reported to the chief engineer through the division of design and construction.

When the chief engineer is the executive officer, the division of accounts should report to him, in order that he may be informed of the fiscal operations of the department.

When a State highway department is in charge of a single commissioner, and a competent civil engineer is selected for the position, the scheme of organization herein outlined will be applicable by substituting in this discussion, the word "commissioner," for "chief engineer."

W. W. CROSBY, M. AM. SOC. C. E.—In an efficient organization for producing physical results from men and materials, the responsibility for the results must be clear—if possible, individual—and the authority and resources in any case must be sufficient, not only to equal or balance the responsibility, but also, in order to be on the safe side and to avoid any arguments in the matter, to be appreciably in excess of the required duties and responsibilities. Mr. Crosby.

In highway work, a division of the consideration is frequently made between Construction and Maintenance, and, perhaps, naturally, up to comparatively recent, if not actually the present, time, the bulk of the investigation and discussion in the United States has seemed to center under "Construction". It is beginning to be realized, however, that "Maintenance" is worthy of at least equal consideration, and that the proper organization of the maintenance forces is of prime importance.

The speaker, after long experience and wide observation of the experience of others, has had at least one conclusion clearly crystalized therefrom. That is, that, not only for the sake of securing prompt satisfaction in the results of the expenditures for labor and materials toward maintenance, but also for the sake of economy and efficiency in the long run, it is necessary to separate the maintenance work from the construction, and thus clarify the responsibility for the proper performance of each.

Naturally, there is no need for a State Commission or Commissioner for the Construction and another for the Maintenance, nor of two Chief Engineers on these lines; the segregation may properly begin immediately below the Chief Engineer, or it may not begin until the Division Engineer, or even the Resident Engineer, is reached. Local

Mr. Crosby.

conditions and due regard for the rest of the whole organization of the department will decide this point. Ultimately, however, the separation of work and responsibilities must be reached.

The speaker has worked up through the matter from the beginning, of all construction work and no maintenance, to the point where the maintenance mileage far exceeded that under construction, and he has tried the various methods of placing the responsibility for the maintenance on the construction engineers, or maintenance engineers, and on others. He has had the maintenance work done by patrolmen, by gangs, by contract, etc.; but satisfaction has been approached only through such arrangements as made the maintenance work and responsibility for its proper performance the sole duty of the employees up to a certain point where dependence could be had on that individual's appreciation of its proper relation to the importance of construction, and on whom the construction demands were not so great as to incite any neglect of the maintenance.

As has been previously stated by the speaker:*

"The importance and economy of prompt, efficient and sufficient maintenance cannot be overestimated in road administration, and this is especially true in the case of modern roads under present traffic conditions. More of the existing defects in roads today, whether such defects be those of appearance, of comfort, or of economy, are due more to weak points in maintenance than to deficiencies in construction or to any other cause.

"The requirements of maintenance work demand the careful performance of little things and the prompt attendance to such; persistence and continuity of action; good judgment and craftsmanship in actual work; and a high regard for economy and the old fact that 'many a little make a mickle'. Maintenance work contains far less of the spectacular than does construction, and thus some other stimulus is frequently needed by the workers in it that interest may not flag. Without some such incentive, the results are almost sure to be unsatisfactory."

Another matter to which the speaker wishes to call attention, in connection with the discussion under Organization, is that of the duties of resident engineers and inspectors.

The differentiation between these two cogs of the machine does not seem to be always as clear as it should be, and frequently, from lack of such clearness, duties seem to be extravagantly imposed on one or to be loaded on the other so as to cause a failure in the operation.

A resident engineer is generally supposed to be a man of some experience and skill in the work under his charge, and who, on account of such expertness, is delegated from above certain (limited) authority for making decisions and for directing the details of his work so as to facilitate the progress of the latter and relieve his superiors from the

* Report to the State Roads Commission of Maryland, 1912, p. 101.

necessity of considering and deciding minor details when once general directions have been issued in one way or another by them. It should be noted that ability, experience, firmness, good judgment, and tact are primary requisites for a satisfactory resident engineer. Mr. Crosby.

An inspector, on the other hand, is merely the eye of his superior, to whom he reports, focussed on the particular work on which he is stationed for the purpose of observing or inspecting its performance. He is instructed, by means of copies of the clauses of the specifications that apply to that work under his observation, or by other means, as to what is required for satisfaction of the contract in such work, and, in case of any apparent evasion or violation of the provisions of his instructions, is or should be directed to call the attention, first, of the contractor and, secondly, of his nearest superior with authority to the matter.

An inspector, as such, has or should have no authority over the work delegated to him, and his responsibility is, or should be, accordingly limited to reporting promptly on the facts as he notes them. To delegate authority to him makes him no longer an inspector but rather a resident engineer of more or less limited field, as the case may be.

It is not the speaker's intention to provoke discussion of the etymology of the two expressions, or to quarrel with their various uses, but rather, by the foregoing, to illustrate differences of meaning that may be assigned to each for the main purpose of clarifying and, as far as possible, lending force to the following remarks.

The speaker (and doubtless those to whom these remarks are addressed) has continually heard references to difficulties supposed to be omnipresent between contractors and engineers, and much time on many occasions has been occupied in discussing such differences or sources of friction and means for their reduction or relief.

From a long experience, in capacities ranging upward from inspector to chief engineer, the speaker has become convinced that the responsibility for such friction rests largely in many cases with the chief engineer or other party responsible for the organization of the engineering forces for highway work.

In connection with the actual organization of the engineering forces, consideration of the specifications for the work itself must not be neglected, for, in part at least, they generally affect the operation of the machine or express in words what is graphically or mechanically shown by the form of the organization itself.

In a lecture at Columbia University a year ago, the speaker made the following statements which it seems to him are pertinent for repetition here:

"With a proper organization of an engineering department, including the definitely understood delegation of authority, the full expres-

Mr. Crosby.

sion of the work to be required by plans and specifications, the location of the responsibility on the proper party (the chief engineer) and this recognition of their obligations on the part of the contractors, ninety-nine per cent. of the present causes of friction between the latter and the engineers would be removed and in place thereof would be substituted the cordial assistance of the engineers to the contractors.

"To hitch up an experienced contractor's foreman, bent only on making money for his employer, on one side of the pole with a young, ambitious but green, inspector (perhaps the only one obtainable) on the other side, and then to turn this team loose and to expect them to keep steadily along the road toward success would be folly, yet it is often attempted, for valuable inspectors do not often remain as such as long as do foremen; but if the foreman realizes that the inspector is to call for help the moment he feels he is losing his footing and that the call will be answered by an experienced man fully capable of handling the situation, there is far less likely to be the need for such a summons. Few competent engineers and contractors cannot get along together peaceably and advantageously. The difficulties seem to come largely from mismatching, by improper delegation of authority, and from lack of clearness and definiteness in describing the work and materials to be furnished.

"The speaker knows from experience the difficulties of the young, enthusiastic, impatient resident in preserving a placid equanimity day after day when constant evidence of a desire on the part of a contractor to evade the specifications, to substitute 'something just as good' for the materials and work he has agreed to deliver, is offered. On the other hand, he sympathizes with the contractor who is constantly being nagged by an inspector over minor deficiencies, or when the inspector tries to 'run the job himself'. Perhaps it is human nature for most contractors to try out an inspector to see what shortcomings he will quietly submit to, and, having found out, to his advantage or loss as may be the case, thereafter to gauge his work accordingly. Perhaps it is natural for most contractors, after competitive bidding on public work, to attempt to substitute at every possible opportunity 'something just as good' for the article specified. But the speaker believes that much improvement in the relations between contractors and engineers would be had were the organization and specifications, as before referred to, made most explicit and then the contractors to regard their carrying out to the letter as much an obligation on themselves as the completion of the work."

Therefore, in framing an engineering organization for highway work, and in drawing the specifications for the work under it, the speaker believes that full consideration should be had, previous to arranging for the resident engineers and the inspectors, of the possibilities of securing competent "residents" for the salaries fixed to be paid; of the possibilities of securing alert and satisfactory "inspectors" for the salaries fixed for these positions; of the competency and character of the contractors likely to carry on the actual work,

and of other conditions likely to affect the decision, and then to design the machine in all its details so as best to fit all the conditions. Mr. Crosby.

It is scandalous for an engineer to design a machine requiring steel in all its parts and then, on that design, to build it of wood because wood happens to be the available material. It will be disastrous to allow the use of wood for a cog when steel is known to be needed, and every cog in the machine, even the least important, should be recognized as needing in its character an ample "factor of safety".

One word further: Such a machine should not be designed or built too delicately or too lightly. The larger and more complicated the machine, the more necessity there is for sufficient mass in the machine parts themselves to take up the shocks and vibrations, from both without and within, incident to its operation. Mass is necessary for momentum, and a sufficient momentum is desirable in this case for the purpose of continuing action in spite of the inevitable obstructions in regular and efficient operation.

FACTORS LIMITING THE SELECTION OF MATERIALS AND OF METHODS IN HIGHWAY CONSTRUCTION.

P. E. GREEN, M. AM. SOC. C. E. (by letter).—One of the rules adopted for this discussion is that the matter to be presented must be new. It is a very proper rule, but it should be realized that it is a very difficult one to live up to. As far as new matter is concerned, it is hard to conceive of a phase of this subject which has not been touched upon or investigated more or less thoroughly, except possibly from the laboratory end. It would appear necessary, therefore, to confine oneself to an academic discussion of the matter or to present individual experiences showing some variation from expected results. In order to bring out a broad line of discussion, it might be well, however, to systematize the factors entering into the problem and call attention to some phases which might be investigated a little more than has been done in the past, with the hope that some important new points may be presented. In opening this subject the writer will confine himself to a general outline of the problem, leaving the details to be discussed by those who follow. Mr. Green.

The subject as assigned may be logically divided into two interlocking general sections, namely: "The Selection of Materials", and "Methods of Construction". Each of these main headings may be further divided into numerous and important parts. All these parts should be taken into consideration by any public authority, such as a city, county, or State, when it is proposed to enter on a general scheme of highway improvement such as is so common at this time. In this way it is not difficult to make a logical selection of the various materials and methods involved in the construction of a system of streets or highways; and a scheme or plan of future construction

Mr. Green.

may be laid out. This does not mean that only one material shall necessarily be selected for any one street or highway. It simply means that the class or type of material shall be selected, and that choice must ultimately be made between several more or less suitable products.

A diagrammatic outline of such a general scheme covering the subject of this discussion is herewith submitted. It is not claimed that it is particularly novel or complete, but is presented for discussion and improvement. Although intended primarily for country highways, it may be used with equal facility for city streets.

DIAGRAMMATIC OUTLINE OF "FACTORS" IN ROAD WORK.

Highways under Consideration.

I.—Selection of Materials.

1.—Character of Road (City or Country).
- Trunk.
  - Through traffic road—commercial or passenger, or both.
  - Commercial road, but not necessarily through traffic.
- Secondary.
- Local.
  - Connecting important centers to trunk lines.

2.—Traffic.
- Much light fast passenger; or
- Heavy hauling; or
- Only local hauling.

Roadway widths required.

3.—Climate.
- Northern.
- Intermediate.
- Southern.

4.—Character of Supporting Country.
- Property values and benefit to be derived.
- Vicinity of large cities.
- Topography—drainage.
- Character of business using road—esthetic considerations.

5.—Materials.
- Class.
  - Superior.
  - Inferior.
    - Physical conditions governing, such as wear, crown, dust, sanitation, etc., etc.
- Cost—maintenance charges.
- Character and appearance.
- Ease of handling materials.
- Relation of material to roadway width.

II.—Methods of Construction.
1. —Laws and legal organizations governing.
2. —Location of railways with respect to improvements—railway rates.
3. —Existing good roads as affecting haul—wagon or truck.
4. —Availability of labor.

Mr. Green.

The scientific selection of the material to be used in the construction of a highway depends on all the items named in the diagram. The diagram itself looks somewhat complicated, but its use is very simple. Before commencing any large scheme of highway improvement, the outline may be studied with reference to materials, methods, etc., and simple tables prepared. Too often some essentials are not considered seriously or are forgotten, and for this reason much money, time, and labor are wasted. From time to time, somewhat similar schemes have been advanced, but frequently they deal with only one essential, such as traffic, to the exclusion of other important elements. For example, in addition to traffic, the character of a city highway should depend on the layout of the city, its topography, population, business, education, and wealth; and, further, the location of the city as regards the availability of standard materials, such as brick, wood block, crushed stone, gravel, sand, tar, asphalt, etc., etc., is vitally important.

Considering the problem of a country highway system, many entirely different factors enter into the selection of the material, such as vicinity of cities, large or small; general population and wealth of the surrounding country; whether or not the highway is to be a trunk line for through traffic, and if so, whether such traffic is light, high-speed traffic, or heavy, low-speed, commercial traffic.

If the highway is a secondary one, as regards the through traffic, it still may be a trunk line as regards its commercial traffic, such as a road leading from a trucking district to any one of our large cities. Such a highway may be comparatively a short one, yet the character of its traffic actually makes it a trunk line.

The least important class of country roads is generally referred to as "local roads". These are exactly what the name signifies, and whether or not they are to be improved depends on the wealth and education of the surrounding country and its inhabitants. Such roads are generally paid for only by local taxation.

The effect of "climate" is more important than is often considered. Some pavements, such as the various bituminous pavements, concrete, etc., are very much affected by the temperature. Thus a surface mixture of asphalt suitable for Chicago is not suitable for New Orleans; and concrete as a wearing surface should do better in Houston than Buffalo.

Three zones may be recognized: Northern, embracing the New England States, New York, Pennsylvania, Ohio, Illinois, etc.; the Intermediate, such as Virginia, Kentucky, Tennessee, Arkansas, etc.; and Southern, such as Alabama, Mississippi, and Texas, which have little winter. In the Northern States, the selection must be of materials not affected by extremes of temperature, freezing and thawing. For the Intermediate, it is not necessary for the materials to withstand great variations in temperature. For the Southern, materials which

Mr. Green. might utterly fail in the North because of inability to withstand extreme cold or great variations in temperature, may be very satisfactory. Furthermore, the exceedingly heavy and continuous rains following long hot, dry spells in the southern sections must be taken into account.

A great deal of money might often be saved by considering carefully the various classes of paving material, which may be suitable for the same purposes and yet may vary widely in cost in the different parts of the country. Thus, wood block pavement may be a very reasonable one for the business streets of small cities in regions close to the sources of supply, but for other cities, similar in size, but not so situated, it would be a grave mistake to use it, because of its prohibitive cost. This same wood block pavement has a characteristic in common with sheet asphalt: it must receive a certain minimum traffic or it may fail. On a wide roadway, having only a traffic along the center, the blocks outside this used strip will curl up under the sun and swell and "blow up" if a rainy fall follows a hot, dry summer.

Further, such a material as trap rock, though making good macadam highways in New York, probably better, as far as wear is concerned, than any of the limestone used in the West or South, would be impossible for these last locations. Yet the writer has seen specifications, for roads hundreds of miles away from granite quarries, which called for granite top macadam, though local limestone at half the cost would wear nearly as well. Again, there are sections of the country where the high cost of cement, but the comparatively low cost of good stone or gravel, makes a concrete base for a pavement quite expensive, but a crushed stone or a natural gravel rolled base would cost less and be nearly, if not entirely, as durable. Of late years, too little attention has been paid to the macadam base as a foundation for a durable pavement. The public has been educated to think that concrete is the only possible foundation. The situation is similar to that of the septic tank in sewage disposal. Many public officials have heard and believe that such a tank turns sewage into drinking water.

In those parts of the country in which there has been much road work and improvement, it is much easier to get competent foremen and good labor than in sections where little, if any, of such work has been done. The result of good workmanship is very apparent. The local officials, also, are better educated in these matters and more inclined to give an engineer sway.

It should be remembered, also, that the character of the highways, whether city or country, must depend largely on the ability of the tax-payers to pay for them. A sparsely settled region may be very desirous of having good roads and be willing to be taxed for their construction, within reason, but Wisconsin, for instance, is far less

able to pay $10 000 per mile for highways than is Massachusetts. The road mileage depends only to a limited degree on the population. Mr. Green.

There can be little question of the benefit derived from the construction of good highways, but the degree of immediate benefit should have much to do with the selection of the material for such improvement. It might be, and frequently appears, that the benefits in the long run from a thoroughly high-class permanent construction will, theoretically, far exceed those derived from any cheaper construction. Because of the large immediate benefit received from the cheaper construction, however, and because the tax-payers are unable to pay for the more expensive construction, it may be much better finance to put in the cheaper highway, and thus not over-burden the community. Future development and growth of wealth may provide equitably for the construction of a better improvement. Is it not the same principle that governed the construction of our early railroads? It is a real recognition of this principle, not altogether possessed by some engineers, that has justified in many cases the voting of long-term bonds for short-lived improvements. Such a principle must be used with caution, however. It cannot be defended in New York or Illinois, but certainly can in Texas and Oklahoma.

In addition to the various points noted thus far, the esthetic features of the wearing surface of a highway should not be forgotten. In many cases, this feature should be made a very large factor in the selection of the proper material. Thus, a smooth, well-built brick pavement might be nearly as noiseless as one of bituminous concrete, and might have a much less maintenance charge and be more sanitary; but, along a scenic highway where the adjoining country is very highly developed esthetically, such as in the vicinity of a large city where there are many great estates, it is quite probable that the bituminous concrete pavement would be considered more suitable, pleasing, and satisfactory by those who pay for it. Such a road would be used largely by automobilists and comparatively little by truck gardeners. If this highway were lined by truck farms, however, could there be any doubt that the selection, if made between the two, should be brick, especially as it has been demonstrated that the bituminous concrete does not withstand iron-tired traffic? This selection, moreover, would be the correct one, even if the pleasure traffic was very large.

One of the points which it is believed has been neglected in the past is the relation of traffic to roadway width, especially where traffic is dense. It seems to the writer that it is possible to establish a logical, if empirical, formula which would be a considerable help at times in the solution of this vexatious problem. Some years ago, in preparing a report on a popular scenic highway near Chicago, a traffic census was taken at various points, and in addition statistics on other popular

Mr. Green.

park highways in Chicago were obtained. These were plotted, together with the various existing roadway widths, and several curves tried on the same sheet. In this manner, it was finally decided that a parabolic curve having the equation:

$$Y = \sqrt{\frac{X}{6}} + 16,$$

would express the desired relation. In this equation, Y = the roadway width, in feet, and X = the number of vehicles.

Thus, if it is determined from a traffic census that within 5 or 10 years a highway will have a probable traffic of 2 000 vehicles, the formula would give a roadway width of 34 ft., as shown on Fig. 1.

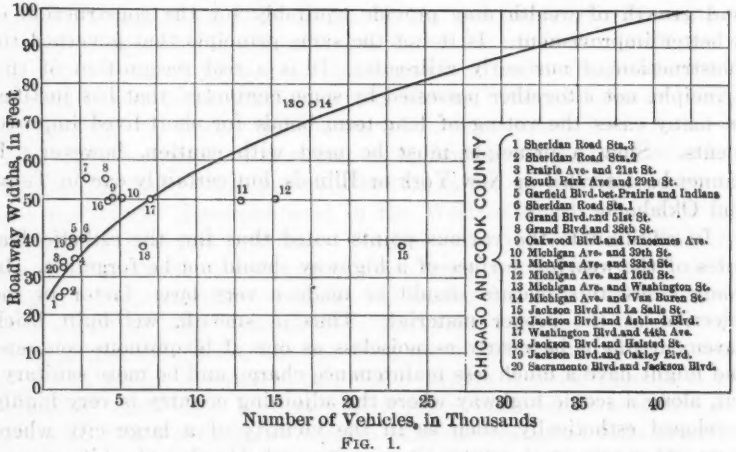

FIG. 1.

The diagram, or formula, is of course faulty as it takes into account only two factors, but it has been a help in arriving at conclusions at times, and is offered for what it is worth.

Attention would be called to the fact that, because it is decided that the roadway is to be of a certain width, say 34 ft., it does not follow that the entire road should be paved with an expensive material. Cuyahoga County, Ohio (Cleveland), has hundreds of miles of roads improved on one side with brick and on the other with plain macadam or gravel. The empty wagon and light horse traffic prefer the latter. Winona County, Minnesota, has paved the central 8 ft. of some of its highways with concrete, and provided wide macadam shoulders.

Mr. Thomes.

E. H. THOMES, M. AM. SOC. C. E.—An important factor in the selection of materials would be a standard specification for gravel, broken stone, etc., so that there would be no misunderstanding as to the sizes referred to; it would also be to the advantage of all buyers

and sellers of broken stone. At present, this material is specified by minimum, maximum, and average lengths or diameters, by passing through a ring in any one or all directions, by the diameters of the screen perforations, by arbitrary designations, and in various other ways. Some designate No. 1 stone as the first course laid, which is usually the large stone, and others designate No. 1 stone as the small stone which first passes through the stone screens. Some refer to nut size, which may be any size between those of a hazel-nut and a cocoanut. The speaker presented this matter to the Association for Standardizing Paving Specifications 3 years ago, and also in more detail to one of the road meetings of this Society 2 years ago, but very little has been accomplished since. His attention was called to this subject at the International Road Congress in London in the summer of 1913 by a report of the work done by the (British) Engineering Standards Committee on the standardization of road material. The report was published in the daily official journal of the Road Congress at London, but very little mention of that work has been made in the United States. Mr. Thomes.

The Engineering Standards Committee is supported by the Institution of Civil Engineers, The Institution of Mechanical Engineers, The Institution of Naval Architects, The Institution of Electrical Engineers, and the Iron and Steel Institute, all of Great Britain. It has issued more than sixty reports and standard specifications, mostly along mechanical and industrial lines. In the summer of 1912 a Sectional Committee on road material was formed. It recognized the need and importance of the standardization of broken stone, and that was the first matter taken up. A sub-committee of the various interests was appointed, and, after considerable discussion and investigation, the British Standard Specifications for sizes of broken stone and chippings was adopted and issued by the Engineering Standards Committee in the summer of 1913.

Stones 1 in. in diameter and less are designated as chippings. There are four standard gauges of broken stone, 1½, 2, 2½, and 3-in. Broken stone specified as 1½-in. gauge shall all pass through a 1½-in. ring, and shall consist of the following percentages by weight: Not more than 15% passing through a 1-in. ring in every direction; not less than 65% more than 1 in., and not exceeding 2 in. in greatest length by measurement; not more than 20% greater than 2 in. in greatest length by measurement. The specifications for each ½-in. larger gauge are similar to the foregoing, with ½ in. added to each dimension stated, excepting the 3-in. gauge where 4 in. greatest length is used. Six standard gauges of chippings are recommended, namely: 1, ¾, ½, ⅜, ¼, and ⅛-in. All 1-in. chippings must be capable of passing through a hole 1 in. square; and at least 70% by weight must be retained by a sieve having holes ¾ in. square. The specifications

Mr. Thomes.

for the other sizes are similar, with the substitution of the sizes of sieves. With ½-in. chippings, the sizes of square holes on which the material must be retained is $\frac{1}{16}$ in.; everything passing that sieve is to be called sand. They also specify gauge plates, sieves, and methods for testing fair samples of at least 100 lb. of the material. It will be seen that in Great Britain the broken stone is divided into more sizes than is customary or advisable in the United States. Some of the quarries there have been developed much longer; they are down deeper, and in sounder and more uniform rock. Some of them also furnish washed chippings, which are advantageous for bituminous work.

The materials and quarry practices in the United States are similar to those of Great Britain, and, with the work already done by the Engineering Standards Committee, it will be an easy matter to obtain a standard specification for sizes of broken stone. The question must be considered from the standpoint of both sellers and users, for all purposes. Conditions here seem to warrant that this subject be taken up by this Society, and in order to secure some definite action on this matter, the speaker will move that the Board of Direction be requested to appoint a Special Committee on the Standardization of Broken Stone, to report to the Society as soon as practical.*

Mr. Whinery.

S. WHINERY, M. AM. SOC. C. E.—The diagrammatic outline of factors in road work submitted by Mr. Green is generally a very satisfactory classification of the elements entering into the design of highways. The speaker, however, would remove the element of esthetic considerations from the subdivision under "Character of Supporting Country" and give it a separate sub-head at the end of the second column. It may be questionable, however, whether this item should have any place in such a diagram, devoted as it is to what may be called the economics of highways. Esthetic considerations, of course, cannot be ignored finally, but, from the engineering point of view, they are foreign to the main problem, which, in highway design, as in other engineering structures, may be reduced to the question: What design will best serve the purpose intended, with due regard to the highest yield in returns on the money invested? Necessity, of course, may force us to substitute the question: How may the highest economical results be obtained for the money available? Esthetics is not a factor in solving either problem.

Nevertheless, it must be finally considered, and the answers to the foregoing questions may have to be modified accordingly. The highway should be designed along the same lines as any other industrial

*This matter is referred to the Special Committee on Bituminous Materials for Road Construction, with the request that some action be taken to secure the standardization of broken stone in the United States.

Mr. Whinery.

structure, as, for instance, a building for manufacturing purposes. Here the efforts of owner and architect will be first directed wholly to questions of utility and economy. These settled, the question of the adaptation of the design to artistic ideas or standards will be considered, and such modifications or additions as may please the designer, or as the owner may feel willing or able to afford, will be incorporated.

In any event, the question of esthetics, however important a factor it may be considered in designing city streets, boulevards, and parkways, is usually so unimportant in as far as it relates to the roadway itself, in the case of country highways, as to be almost negligible.

The speaker cannot agree with Mr. Green that the building of temporary, inadequate highways is justifiable, except in rare instances, especially where long-period bonds are issued to pay for them. In the present well-developed status of scientific highway construction and economics, and the possibility of securing capital for enterprises of real merit, the spending of the public money for highways of temporary life and usefulness is generally inexcusable. Mr. Green's citation of early railroad history does not present a parallel case. The temporary and inadequate railroads built in the early days resulted from the undeveloped conditions of the principles and requirements involved, rather than from financial or economic considerations. Intelligent and reasonable people do not pattern after them now, to the extent of adopting an ephemeral and clearly inadequate construction, which must obviously be abandoned and reconstructed in a few years. It would be more difficult to finance such an enterprise than one properly designed to serve adequately the prospective requirements of the reasonably near future.

As a business proposition, the speaker does not believe that it is wise or justifiable to issue long-period bonds to pay for a structure the useful life of which will be but a small fraction of the period the bonds are to run. In other words, we have no ethical right to saddle upon posterity a burden from which posterity will not be benefited. From the sound business standpoint, a highway improvement the benefits from which will not redeem its cost during its life, is not a justifiable investment for a community or a State.

This, however, is not an argument in favor of unnecessary or reckless expenditure in the building of a highway. No more money should be expended on it than the conditions or needs of a community, or the general public, now economically justifies or is likely to justify during the life of the improvement. The strict application of this criterion would rule out the costly improvement of many ordinary highways where a properly constructed dirt road is all that the conditions warrant.

The considerations relating to selecting the type of roadway and the materials to be used in its construction, submitted by Mr. Green, are

Mr. Whinery.

in the main apropos and sound. It would have been appropriate for him to add a warning against the use of materials, merely because they are of local occurrence, or because of their cheapness, and a strong protest against the use of materials or methods the utility of which has not been sufficiently established by experience. The use of experimental materials and methods, except on a very small scale for trial, ought to be discouraged by the prudent engineer. Progress demands, of course, that promising innovations from established practice shall be tried out, but the conservative engineer will prefer to let other people do the experimentation, except on a scale which will not result in any considerable loss to his clients, in case of failure.

Personally, the speaker feels that, in road and pavement work, we ought to adhere pretty close to materials and methods the value of which has been clearly established.

The more important country highways are now subjected to very much the same conditions of use as the average city street. Long experience, both in America and abroad, has, after thorough trial and much foolish and often disastrous experimentation, determined that certain types of pavement and certain materials, can alone be depended on to produce satisfactory results, and their use on city streets has become standard. Among these the choice, of course, will be influenced by local conditions. Prudence and good engineering would seem to dictate that we should apply this experience and established practice to the construction of modern roads. The common argument that the first cost of a standard roadway pavement is too great to warrant its use is in most cases fallacious or untenable. An established highway is, nearly always, a permanent structure, and should be designed with reference to its true economy, that is, its value as an investment. If, for instance, a standard brick-paved roadway will last 20 years where a water-bound macadam surface will last but 5, and the former can be maintained at a less annual cost, it will be, at ordinary prices, much the more economical in the end, and the engineer should make this plain to his clients. He should vigorously discourage the common disposition of the public to waste its money on temporary highway improvements because of their low first cost, and should encourage the building of roads in such a manner as will prove most truly economical. These are such trite arguments that they seem to need to be repeated until their truth is accepted and more generally acted on.

The speaker agrees with Mr. Green that the width of the paved roadway should be determined with reference to the density of travel to which it is likely to be subjected, but thinks that the tentative formula submitted for determining the proper width, when applied to country roads, should be used with even more caution than the word tentative implies. The data on which it is based seem to have been

derived from conditions on very heavy traveled streets, boulevards, and suburban roads, where the conditions are very different from those on most country highways; but, even in the examples used, there is such a wide variation in the figures as to suggest their uselessness as a basis for determining a standard of width of roadway. Thus, as nearly as can be determined from the diagram (Fig. 1), the number of vehicles per foot of width of roadway varies from about 35 to more than 600. Mr. Whinery.

It is doubtless true that the higher figure indicates dangerous crowding, but, even so, a roadway having only 6% as many vehicles per foot of width cannot be regarded as an appropriate factor in determining a proper and safe standard for allowable density of travel.

If the proper width is to be determined by this method, only observed data, from such highways as seem to have just about the quantity of travel they can safely and conveniently accommodate, should be used. Deductions or formulas from such observations would be far more useful and trustworthy than the theoretical considerations and conclusions that some have tried to work out and apply. It is very desirable that data from highways of the character mentioned should be collected and collated.

W. W. CROSBY, M. AM. SOC. C. E.—Mr. Green is to be complimented on his interesting presentation of this subject and on his exposition of the factors involved in the selection of the materials or the methods of construction. His diagrammatic outline of factors in road work is most interesting, and if one will take the trouble to compare this diagram with that submitted by the speaker 3 years ago,* an interesting illustration will be afforded of the ideas in common as well as those of difference which may be held by two individuals. Mr. Crosby.

The speaker has been particularly interested in the scientific solution, proposed by Mr. Green, of that troublesome problem, the determination of the proper width of a roadway, and desires to express his belief that it is this sort of treatment of many of the present questions in highway engineering that will do most to advance the status of this particular branch of the profession and to erect for its future growth a substantial foundation.

In reference to this matter, and with the hope of furnishing data for the basis of such treatment of some of the problems connected with the selection of materials and methods in highway work where the traffic factor seems preponderating, the speaker offers the following concerning traffic records in general and in a particular instance coming under his observation:

In 1903 he urged highway engineers to take traffic censuses and study the relations between traffic conditions and the life, or ex-

* *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 6.

Mr. Crosby.

pense for maintenance, of road crusts. He also suggested that from the study of such relations much might be learned that could be used advantageously in making selections for construction under known or determinable traffic and other conditions.

The Illinois Highway Commission began this traffic census in 1906. In 1909, the Massachusetts Highway Commission took a census of traffic on Massachusetts roads.* Other traffic censuses have been taken and reported by officials and individuals from time to time since these dates, and though at first there was some skepticism as to the value of such investigations, the speaker believes that there is now a fair amount of general agreement that, with proper deductions made therefrom, they are of great value. He also believes that there is general agreement now that a road crust satisfactory and economical for sustaining rubber-tired motor traffic may not be so, either for horse-drawn or for hard-tired traffic, and *vice versa*, as he has stated previously.

During the summer of 1913, in order to permit the improvement of a highway by the State Roads Commission of Maryland, the Board of Park Commissioners of Baltimore opened to all kinds of traffic a park road paralleling the Reisterstown Turnpike for a distance of 2 500 ft. Previously, this park road had been kept in excellent condition by the maintenance, on the quartz-schist macadam, of a bituminous (or "pitch") surface, at an annual cost of about 9 cents per sq. yd. Within 90 days after the opening of the road to all kinds of traffic, this surface or "carpet" became in dry weather a dusty mass of loose material and in wet weather a mess of slimy black mud an inch or more thick. Depressions in the macadam beneath also began to show soon afterward, and by December, 1913, the road crust appeared to be generally going to pieces. The quartz-schist had shown a rattler test of about 4, though its cementation power, in use, had proved to be high—probably due to its iron content.

Southward from this 2 500-ft. stretch, the pleasure traffic continued along the main road through the park, the commercial traffic, which consisted mainly of horse-drawn, hard-tired vehicles and motor trucks, being turned out of the park at this point. The traffic on the 2 500-ft. stretch before its opening to commercial vehicles was therefore equal to that now using the road southward from this stretch, as shown by the census under "B" in Table 1; the combined traffic on the 2 500-ft. stretch is that shown under "A".

The carpet referred to in this case was made up by successive applications, in 1911, 1912, and 1913, of "75% Asphalt Oil", the layer of each being covered with pea gravel or stone chips, and at the time of its first subjection to the new traffic it was about ¼ in. thick on top of the macadam. The last application of bituminous material (or "pitch compound") and stone chips was made the day before opening the

* Report, Massachusetts Highway Commission, 1909, p. 128, etc.

road to mixed traffic. The width of the carriageway, exclusive of gutters, is 22 ft. Mr. Crosby.

The figures of the traffic census taken in 1904 are inserted in Table 1 in order to give an idea of the increase or change in character of the traffic between that time and the present. They also give some information as to the amount of traffic under which a water-bound macadam of comparatively soft broken stone may be maintained satisfactorily at a not excessive cost. Such a road crust in this instance required treatment with a pitch compound before the traffic reached the figure in "A", in order to permit its maintenance with satisfaction at any cost.

TABLE 1.—TRAFFIC CENSUS ON MAIN ROAD IN DRUID HILL PARK, BALTIMORE.

Classification	Maryland factor.	November 24th to 30th, 1904.		November 20th, 1913.			
				"A"		"B"

In making deductions from the data in Table 1, it may be of interest and value to refer to the similar data and the conclusions thereon,* furnished by the speaker a year ago concerning the Park Heights Avenue experimental work.

One further point may be indicated. It will be noted from the traffic tables that the increase in traffic on this section, due to the admission of commercial vehicles, was 204 units of horse-drawn and 364 units of motor traffic, the latter being composed mainly of motor trucks. Both these types have a high abrasive or crumbling effect.

* *Proceedings*, Am. Soc. C. E., for September, 1913, p. 1702 *et seq.*; or *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 188 *et seq.*

Mr. Crosby. Evidently, the thin carpet over the soft macadam stones was unequal to the task of maintaining its integrity under this traffic, or of absorbing the shocks coming on it sufficiently to prevent the disintegration of the stones under it. Hence, under this traffic, the stones were abraded or broken to pieces, the bond of the carpet to the stable foundation was thus destroyed, and the carpet itself aided in going to pieces. The actual destruction proceeded along these lines, the carpet first scaling off in spots and revealing in these places a ground-up condition of the macadam surface beneath. Then the scales of the carpet, thus loosened, disintegrated, and finally the whole carpet went into dust or mud.

The experience here, as well as in some other cases with similar conditions coming under the speaker's observation, is quite similar to many instances of the failure of thin carpets on concrete roadways, and supports the theory that, with friable bases, the carpet must have such thickness and character as will prevent the disintegration, under the shocks of traffic, of the surface of the base itself, if successful maintenance is to be had.

Mr. Brooke. MARK BROOKE, ESQ.* (by letter).—There is no one best paving material for all conditions, and the necessity of carefully considering in each case the many factors shown with such definiteness and detail in Mr. Green's diagram cannot be emphasized too much. As Mr. Green has stated, the use of that diagram in practice is comparatively simple, for it will be found that the choice in many cases will be restricted either by limitations of first cost or by local or general conditions which automatically cut out certain materials from consideration.

In contradistinction to the bridge engineer, for example, the highway engineer often finds that the sum of money placed at his disposal is not based on his own estimate of a definite project, but that he is allotted, in a general distribution of funds based on anything except a careful estimate or budget, a lump sum of money which he must spread over a certain section to the best advantage of the entire area. The question is then, not what is the best material, but how much he can afford to spend on a given street or road, so that the problem is apt to resolve itself into a selection of materials for the most suitable pavement which can be constructed for a definite limited sum, say, for $1.25 per sq. yd. Even in this narrow field of choice careful consideration should be given to all the items in the diagram, as far as the limitation of cost will permit.

Again, it will be found possible to simplify the selection of materials by applying once for all such of the factors in the diagram as have a general and permanent application in any given locality, thus elimi-

* Captain, Corps of Engineers, U. S. A.; Assistant to Engineer Commissioner, District of Columbia.

nating a large class of materials, and restricting the choice to a few types. Mr. Brooke.

In Washington, for example, as a result of experience and of consideration of the various factors such as first cost, character and volume of traffic, suitability of local material, esthetic considerations, etc., the problem has been reduced to a selection of one of three types of asphalt pavement for city streets, and bituminous concrete, cement concrete, or water-bound macadam with a surface treatment of light tar or oil, for suburban streets and county roads.

In the city practically nothing is used but a standard sheet-asphalt, a very limited quantity of 2-in. asphalt block, and an increasing quantity of bituminous concrete in accordance with the specification of the department.

This bituminous concrete, which is very similar to the various pavements of that type laid between 1870 and 1880, appears to have all the advantages and but few of the defects of sheet-asphalt, and is cheaper.

A gravel cement concrete base is now being used under all pavements, except in a few instances where old macadam roads have been surfaced with bituminous concrete.

Macadam, especially an old macadam road, will make an excellent base which will outlast any bituminous wearing surface yet devised, but it cannot be kept free from local settlements, nor can it be easily or economically resurfaced. The man who lays bituminous concrete on a macadam base should realize that he is storing up trouble for himself or his successor 15 years hence.

Whether or not it is advisable to invest in the more expensive base to reduce the cost of future resurfacing is, of course, a question every one must decide for himself.

The engineers in Washington for some time past have been of the opinion that it is better, as a general practice, to lay a base which will not have to be destroyed every time a new surface is put on it, and hope to relieve their successors of the extra expense and difficulties encountered during the last 10 years in resurfacing pavements laid on macadam and bituminous macadam bases—types of construction which conformed to the best engineering practice of the time, when the use of Portland cement was still in its infancy.

For 30 years a concrete base has been laid without either longitudinal or transverse joints, with no significant bad results, and the writer doubts very much the necessity of the elaborate and costly provisions for such construction which are so often seen in cement road work. On some of the cement pavements in Washington, no joints whatever have been provided, on others there is a thin transverse joint every 50 ft., made by bringing the concrete up to a vertical face, laying a strip of folded tar paper against this face, and then depositing the

Mr. Brooke.

next batches against the paper. Thus far, no difference in the action of the two classes of construction has been observed. If any joint is used it should be as thin as possible. A wide joint is a weak joint, and its partial contraction will invariably force the filler into a pronounced ridge, as objectionable to motor traffic as any thank-you-ma'am.

When this pavement is laid with a curb it is kept about 1 in. below grade, so that, should the thin bituminous carpet with which it is covered prove an uneconomical form of wearing surface, the pavement can be used as the base for a thicker surface of bituminous concrete and still have sufficient face of curb showing.

For many years trap rock has been the standard material for water-bound macadam. Recent experiences in the oil and tar surface treatment of trap and limestone roads indicate that, for moderate traffic at least, the surface treatment does as well with the limestone as with the trap, and the saving effected by using limestone about offsets the first cost of the surface treatment.

Referring to the practice mentioned by Mr. Green, of paving the center 8 ft. of certain roads with concrete and providing wide macadam shoulders for the light traffic, the writer believes it is a mistake not to make the paved strip wide enough to carry two lines of traffic. If this is done, it is unnecessary for passing vehicles to cross the joint between the concrete and the shoulders—the weakest part of the road—a condition which would be particularly objectionable at seasons when the earth shoulders were unsuitable for traffic, and all vehicles would seek the paved portion of the road. The engineers in Washington have had this experience in the case of a trunk-line road paved with granite block, the center 8 ft. of which was laid with asphalt for the benefit of light traffic. As a matter of fact, all traffic, both slow and fast, tries to get on and stay on this 8-ft. strip, thus increasing both the congestion of traffic and the wear on the asphalt.

The absence of any numerical weights assigned to the factors in Mr. Green's diagram appeals to the writer as being most sensible. The relative values to be given these factors in selecting a material must be different for each case, and a table which attempts to fix values for general application is apt to be misleading.

Materials and methods successful in one case are failures in another, and the lack of knowledge or realization of the difference in conditions in the two cases often leads one to draw general conclusions which are not warranted.

To attempt, with present knowledge, to solve road problems by the use of general formulas or tables is, as a well-known highway engineer has described it, "simply holding at arm's length work which should be brought close to us".

By careful study and accurate records of failures and successes, by standardization of specifications and tests, and by uniformity in

methods of taking traffic censuses, one can largely eliminate the elements of personal taste and judgment in the consideration of the various factors under discussion, and still further simplify and standardize the selection of materials. Mr. Brooke.

EQUIPMENT AND METHODS FOR MAINTAINING BITUMINOUS SURFACES AND BITUMINOUS PAVEMENTS.

WILLIAM R. FARRINGTON, M. AM. SOC. C. E. (by letter).—The maintenance of bituminous surfaces and bituminous pavements is divided naturally into three stages. The first includes what is usually classified as ordinary maintenance, such as patching, covering, etc. The second covers re-treatment of the surfaces and the renewal of the seal coats on the pavements; and the third includes the re-shaping or re-surfacing of roadways carrying bituminous surfaces, and the re-surfacing or reconstruction of the pavements. Mr. Farrington.

The writer will discuss the work with which he is familiar, on roads outside the cities and large centers, and will consider the equipment needed and the methods to be followed in maintaining bituminous surfaces consisting of hot or cold oil, or tar, and sand, gravel, or chips; also, bituminous pavements composed of broken stone and tar, oil or asphalt; or of sand and oil.

It is not intended to take up the cost of maintenance, for though this cost might be regarded as a criterion of suitable equipment and proper methods, it probably varies so much in different localities that, after all, a comparison of costs is not of much value in a general discussion, unless the conditions are well understood and the prices paid in any locality are known.

It is assumed that maintenance work will usually be handled by a department with its own gangs and equipment, rather than by contract, except possibly in case of extensive re-surfacing.

Patching.—For patching, only a small gang is needed, and the equipment is simple. There should be one or two portable melting kettles, a small portable tool-house, and one or two small tents for the laborers, unless a van is provided.

The methods to be followed in patching the different kinds of surfaces and pavements are much the same. Generally, one should use the same kind of bituminous material for patching as was used in forming the surface, and ordinarily it is not advisable to select a much heavier grade, except with stone, slag, or chips, for filling depressions.

In the writer's opinion, only the lightest, or so-called dust-laying, oils or tars, should be used without the addition of some grit; and, even with these, a light covering is probably economical. If applied

Mr. Farrington.

without covering, however, patching is usually not advisable, as the cost of an additional application is small.

In patching an ordinary oil or tar surface, one should first attend to the depressions. Slight depressions can be filled with oil, or tar, and sand, gravel, or chips; but if they are deep, stone or slag should be added. The depressions should be cleaned, and the edges cut out if necessary, in order to allow a thorough bonding of the new and old material.

Although the best results are obtained by mixing the bituminous material and sand, or stone, etc., before applying, satisfactory results may be obtained without mixing, if the work is done carefully. In filling slight depressions, where the materials are not mixed before applying, a thin coating of oil or tar is spread over the bottom and covered with sand, gravel, or chips. If stone or slag is used with oil for filling deep depressions, the stone or slag is spread over the oil with which the bottom has been coated, then more oil is applied and covered with grit. If tar is used, the methods are similar, but more bituminous material is required.

After filling the depressions, any bare places, or places where the bituminous surface is practically worn through, should be coated, the surface first being cleaned and grit being spread over the oil or tar. In no case should much more than ½ gal. of bituminous material per sq. yd. be used for coating the surface, as any surplus oil or tar will result eventually in the rolling of the surface and the formation of bunches.

Most of the so-called cold tars may be applied without heating, as may the lighter grades of the so-called cold oils, or road oils; but the heavier grades must be heated in order to give the best results in patching.

A much heavier oil or tar than that used in the surface is inadvisable for patching, yet a somewhat lighter grade may be used. Excellent results are obtained by patching a hot oil or tar blanket with the heaviest cold oil or tar, and with these there is much less chance for the formation of bunches than with the heavier materials.

If a pavement composed of stone and bituminous material is constructed properly, not much in the way of maintenance should be required for some time, but depressions will develop eventually, and some patching will be needed. In patching bituminous pavements, including those composed of sand and oil, the methods are similar to those for a bituminous surface, except that, with the sand and oil pavements, deep depressions should be filled with heavy oil and sand, properly heated and mixed before applying; or, if the heavy oil is not available, or there are no facilities for heating the sand, an oil similar to that used for surface work will give good results with slag or cinders, without mixing.

Mr. Farrington.

Covering.—On any bituminous surface, and especially one in the formation of which oil is used, more or less covering with sand, gravel, or chips will be required, either to take up free oil or tar, which will work to the surface for some time after it is applied, or later to prevent the picking up of the surface, which may soften under certain conditions. Covering is also partly a remedy for the slippery condition incidental to any bituminous surface during cold weather.

Re-Oiling or Re-Tarviating.—For re-treating a bituminous surface, practically the same equipment is required and the same methods should be followed as for the original treatment, except that usually less bituminous material is needed.

The life of a bituminous surface, or the length of time elapsing before re-treatment is necessary, will depend on local conditions, and the amount and kind of travel, etc. Where conditions are favorable for such treatment, however, and the travel, especially the horse-drawn travel, is not too heavy, a bituminous surface consisting of grit and about $\frac{1}{2}$ gal. per sq. yd. of the heaviest hot oil suitable for blanket work should last from 3 to 5 years without re-treatment, if patched occasionally and otherwise maintained properly. In re-treating such a surface, not more than $\frac{1}{4}$ gal. of oil per sq. yd. should be used, unless practically all the original surface is gone; and it is not economical to delay re-treatment until this point is reached, as without the protection of the bituminous surface, the road metal will tend to ravel and the roadway to disintegrate.

A bituminous surface formed by the application of from $\frac{1}{8}$ to $\frac{1}{4}$ gal. of light oil per sq. yd., with a small quantity of covering, will last at the best not more than one season, and it will probably be necessary to cover such a surface quite heavily in the fall in order to carry it through the winter and until another application is made the following year. Where from $\frac{3}{8}$ to $\frac{1}{2}$ gal. per sq. yd. of the heaviest cold oil is used with grit, re-treatment with about the same quantity of oil will usually be necessary the second year; but, after that, the application of from $\frac{1}{8}$ to $\frac{1}{3}$ gal. per sq. yd. per season should be sufficient, and an application may not be necessary each year, although, if omitted, the patching will naturally be increased.

If refined coal-gas tar is used, about $\frac{1}{2}$ gal. per sq. yd. is required during the first and second seasons. After that, with cold tar, a $\frac{1}{4}$- to $\frac{1}{3}$-gal. application will usually be necessary each season, although the yearly application may be omitted occasionally. With hot tar, ordinarily a $\frac{1}{4}$- to $\frac{1}{2}$-gal. application should be made every second year. Where unrefined water-gas tar is applied, two $\frac{3}{8}$-gal. applications are advisable each year; but, if only one $\frac{1}{2}$-gal. application is made, a considerable quantity of patching will be required.

As to equipment, for handling the lighter grades of bituminous materials, one or two distributor carts and a pump for transferring

Mr. Farrington.

these materials from the tank-cars are required, and there should be a tool-house, also tents for the laborers, unless vans are provided.

For handling the heaviest grades of oil or tar used for surface work, the following plant is needed:

One 10- or 12-ton steam roller,
One portable heating boiler,
One steam pump,
Two steel tank-wagons,
One pressure distributor (if mounted separately, or two if attached to the tank wagons),
One or two watering carts,
One 2-horse sweeper,
One portable tool-house, and
Two large tents or vans for laborers.

As to distributors, for handling the road oils or the corresponding grades of tars, a gravity machine may be used with good results, if the bituminous material is broomed after it is applied; but the cost of distribution will be less and the results more satisfactory if a pressure distributor is used. For this work, a distributor cart with a pump mounted on a frame back of the tank, and connected by chain with a large sprocket bolted to one of the rear wheels is most satisfactory. Under favorable conditions, good results have been obtained with gravity machines in distributing even the heaviest grades of bituminous materials for surface work; but the chances of failure, if the conditions are not favorable, are such that they should always be applied by pressure distributors if possible. The distributor just described, or one with a gas-engine pump mounted either on the tank-wagon or on separate gear, may be used, but one operated by steam will give the best results. One advantage of the steam distributor is the possibility of cleaning out the pipes and nozzles by blowing steam through them. Of the steam distributors, there seems to be little choice between the one using the direct pressure of steam in the tank for distributing and the pump type, each having its advantages.

To facilitate covering, the sand or other material should be piled in advance on the side of the road.

Before commencing to distribute the bituminous material, the surface should be cleaned with a horse sweeper, and with hand-brooms, if necessary. Any depressions should be filled and the surface patched as needed.

Where the heavier grades of oil or tar are used, it is well to water the old surface before distributing the new bituminous material, but watering is not necessary with the lighter grades unless the surface is unusually dry.

Mr. Farrington.

It is advisable to cover the bituminous material lightly at first, applying more grit as needed, for though some bituminous material will take up only enough grit to form a good mixture, without reference to the quantity put on, in other cases, if there is surplus covering, the oil or tar will continue to work up until the mixture is weakened to such an extent that the best results cannot be obtained.

Seal Coats.—Although a seal coat or wearing coat may not in all cases be necessary on pavements composed of broken stone and bituminous material, the writer believes that it is economical and should usually be applied, either in connection with construction, or later, except possibly where asphalt is used in the pavement. The equipment and methods for applying or renewing such coats are similar to those for the re-treatment of the surface; but, unless asphalt is used, the bituminous material for the seal coat should be of a lighter grade than that incorporated in the pavement. Oil may be used with good results on a tar pavement, and is advantageous, in some cases, in that it is less slippery than tar and also acts to some extent as a dust absorbent.

Re-Shaping or Re-Surfacing.—Although a surface consisting of grit and suitable bituminous material will carry ordinary travel and relieve the road metal of much of the wear, it alone is not a permanent form of treatment. As a result of the gradual wear of the road metal, and because repeated treatment and patching with bituminous material will cause the formation of bunches and an uneven surface, re-shaping or re-surfacing of the roadway will be necessary, eventually.

When this stage is reached it is always well to consider a more permanent form of pavement; for it is an established fact that a bituminous surface will not carry a large amount of horse-drawn travel, and will fail under certain conditions which the writer believes are not as yet clearly understood; and although a bituminous surface may have been satisfactory in a certain locality in the past, the conditions may change or the travel increase largely.

It is assumed, however, that there will not always be money available for the construction of a bituminous pavement, in which case the alternative is the re-shaping or re-surfacing of the roadway and the application of another bituminous surface.

The equipment needed for re-shaping or re-surfacing work, to be done in connection with re-oiling or re-tarviating, is the same as that for re-treatment, except that two steam rollers will be needed, also a straight-tooth and a spring-tooth harrow.

If stone is to be crushed, there should be a portable crushing outfit.

Mr. Farrington.

In re-shaping or re-surfacing a roadway with a bituminous surface, the old surface should first be thoroughly broken up with the roller picks or a scarifier and removed with stone forks.

The loosening of the road metal, partly accomplished by the roller picks or scarifier used in breaking up the surface, should be completed with a straight-tooth harrow, the use of which also tends to shake the worn out material to the bottom. This should be followed by a spring-tooth harrow, which, because of the curved teeth, will bring the stone or larger particles of road metal to the top. The surface should be shaped with rakes, any new stone or other road metal needed should be put on, and the road watered and thoroughly rolled. If any considerable quantity of new stone, etc., is used, the voids should be partly filled with sand, stone screenings, or chips; but, if only a small quantity of new road metal is put on, there will usually be sufficient fine material in the road to bond it.

Either a macadam binder or the heaviest road oil may be used, but, ordinarily, the former will give the best results. About ½ gal. of oil per sq. yd., should be used in two applications, with a covering of grit after each.

Ordinarily, it is not advisable to use tar for such re-shaping or re-surfacing work, unless a bituminous pavement is to be formed by penetration. In this case, usually more new stone or other road metal is needed, and the voids for about 2 in. below the surface should not be filled with fine material. For grouting 1¼ gal. of heavy tar should be used, and a seal coat should be formed by the application of about ½ gal. of a lighter tar with grit; or, if preferred, asphalt may be used instead of tar.

The foregoing description of maintenance work applies to a bituminous surface on a roadway of broken stone, slag, or screened gravel, rather than to such a surface on unscreened gravel; but though the methods for handling a surface on the latter form of roadway are somewhat different, mention can only be made of the fact that although, for the first application, one should use a fairly light grade of bituminous material which will penetrate somewhat below the road surface and thus form a real bond between the bituminous material and the gravel, heavier grades of oil or tar may be used, with good results, for later treatment.

Re-Surfacing of Bituminous Pavement.—In a discussion on maintenance, it does not seem advisable to devote much space to the re-surfacing of bituminous pavements, because such work is probably better classified as reconstruction than maintenance, but attention is called to the fact that the life of pavements composed of broken stone and bituminous material is as yet problematical on roads outside of cities

and large centers, because such pavements have been in use, under these conditions, only a few years. Mr. Farrington.

Storage and Repairs.—Incidental to a consideration of equipment is the question of proper care and up-keep of the outfits. There should be at headquarters, a suitable storage place, with sufficient equipment and proper facilities for making ordinary repairs. It is not only advantageous to have the repairs made by or under the supervision of those responsible for the apparatus during the working season, but, by having the work done by men from the regular force, it is possible to keep the most competent men busy during the winter.

If the amount of work done warrants the employment of a storekeeper, there should be kept at all times, at the storage place, a sufficient stock of tools, etc., to supply the needs of all the gangs.

Reports and Accounts.—It is not possible, in the time at the writer's disposal, to consider in detail the question of the reports, records, and accounts which should be kept on maintenance work. The writer believes, however, that although a consideration of cost is not of especial value in a discussion covering work in widely separated localities, a comparison of the cost of work in different localities in one section is valuable, and is necessary in order to determine what equipment and methods are most economical, and also whether the work is handled efficiently.

Daily reports giving details of the labor cost should be submitted by the foreman, and a record of these, as well as of bills for materials, supplies, etc., should be kept in such a way that the cost of the different kinds of work can be easily ascertained at any time.

H. B. PULLAR, ASSOC. M. AM. SOC. C. E. (by letter).—The methods of maintaining bituminous surfaces and pavements are unquestionably of great importance. Mr. Farrington has covered very fully the matter of maintaining bituminous surfaces and bituminous roads constructed by the penetration method. He has stated that he does not consider it advisable to devote much time to the re-surfacing of bituminous pavements. Although it may not be advisable to devote much time to the total re-surfacing of bituminous pavements, much more might be said regarding their maintenance and repair. The method and equipment necessary for repairing sheet-asphalt and asphaltic-concrete pavements in small towns and cities have been of great importance, and it is on account of the fear of the cost and trouble in making satisfactory repairs that many small towns have given preference to brick, block, and other types in place of bituminous pavements. If proper care is taken and proper equipment is secured, there is no more trouble, nor any greater expense, in repairing bituminous pavements satisfactorily than with Mr. Pullar.

Mr. Pullar.

any other kind. Methods and equipment necessary for repairing these pavements will be discussed later.

It has only been within recent years that much consideration has been given to the repairing of sheet-asphalt pavements. Until recently, the only thing which could be done was to cut out the bad part of the pavement and replace it with new. On streets where the total repairs are more than 50 or 60% of the pavement, this is still the best method. Where this plan is used, all the bad material should be cut out, the edges of the old pavement should be carefully painted with the pure bituminous cement, and then the new material should be put in by a method similar to that used in constructing the pavement. As Mr. Farrington states, an effort should be made to make the repairs with materials of the same class as those used in the original pavement. In the larger cities, or wherever it is possible, the most economical way to obtain the mixture is from some paving contractor. In smaller cities it is advisable to obtain one of the small mixing plants which are on the market and now available. The "Rapid" mixer has proved to be of exceptional value for this work, and is now used by a number of cities in the Middle West for repairing both sheet-asphalt and asphaltic-concrete pavements.

For sheet-asphalt pavements, in which only small depressions or waves appear, the most economical and probably the best method is to burn off about ½ in. of the top and make the repairs by what is known as a "skin patch". This method has been used very successfully in various parts of the country, and there are a number of excellent burners on the market. The burning can be done at about the same expense as would be involved in ripping up the pavement, and in this case it is only necessary to put on a patch about ½ in. thick, instead of cutting out and replacing the entire thickness of the pavement.

The "Lutz" heater method for repairing is based on the same principle—burning off a small quantity of the top surface and replacing it with a "skin patch". The surface is heated by a hot-air blast, and claims are made that no injury is done to the pavement, with the exception of the upper ½ in. which is removed. This heater has been used successfully by a number of the larger cities for re-surfacing work, and it is possible to repair about 500 sq. yd. per day with one machine. Care and experience, however, are necessary to repair or re-surface pavements properly by burning. It should not be attempted by anybody without some knowledge of the proper method. It is not a method which can be recommended for general use in small cities or towns, or on public highways.

During the past few years many attempts have been made to remelt and use the old material for repair work, but, up to the present time, no successful method has been developed. The Noyes crushing machine has been used successfully for pulverizing the old material,

Mr. Pullar.

but the reheating has proved a difficult matter, and thus far has not met with success. The material, after being pulverized by the Noyes crusher, can be used to a considerable extent in a binder mixture, and this idea is being adopted in a number of places. Some of the small mixers claim to be able to re-melt old material satisfactorily, but in nearly every instance considerable burning takes place.

About 2 years ago the writer made a new experiment in repairing sheet-asphalt pavements. The section of pavement to be repaired was very badly cracked, and contained three holes, each about 1 sq. yd. in area. The holes were first cleaned out and the edges trimmed. Stone, ranging from ¼ to 1 in. in diameter, was then placed in each hole and tamped, and to this there was applied about 1 gal. per sq. yd. of a heavy asphalt binder. Chips were then spread over the surface and thoroughly tamped into the voids. Then a squeegee or seal coat was applied over the entire surface, including the stone patches. A recent inspection of this small strip of pavement showed that it was still in excellent condition, so that, without question, this method has already prolonged the life of that particular piece of pavement 2 years, and from indications, will continue to prolong its life another 2 or 3 years. On account of the success of this experiment this method has been used for repairing sheet-asphalt pavement in two or three other small cities in various parts of the country, and up to the present time, reports have been very favorable. This method could be used very satisfactorily in small towns and villages, and would be much more economical than the use of brick or cement for repairing bituminous surfaces.

In repairing asphaltic-concrete pavements of various types, the best method is to use a small mixing plant, such as the "Rapid" mixer, or other small mixer of similar construction. The nominal cost of these machines and the ease with which repairs can be made, will probably result in their more general use for repair and maintenance work.

There are two principal causes for trouble with bituminous surfaces consisting of the superficial treatment by use of tar, oil, or asphalt. One is the fact that, in a number of instances, too much bituminous material has been used. This produces a pavement which is very apt to rut or become wavy, and it is also very disagreeable to the eye. The other source of trouble is due to lack of sufficient bituminous material, or too great a length of time intervening between treatments. If the surface is carefully inspected at frequent intervals, and treated at the proper time and with the proper quantity of material, the road or pavement can be kept in excellent condition at a small cost.

The writer agrees with Mr. Farrington in the statement that it is not advisable at present to discuss the cost of maintenance, as this

Mr. Pullar.

varies considerably in different parts of the country, and, to a great extent, depends on local conditions. Cost data would be valuable even when work in different localities is considered, provided there was a standard system for giving cost, and one which would take care of different units. The total cost per square yard is of little importance unless unit costs are given. A standardization of a system for giving cost data, in both paving and road construction, and in paving and road maintenance, is greatly needed, and much valuable work could be done by a committee of engineers appointed for this purpose.

The question of equipment and methods for maintaining bituminous surfaces and bituminous pavements, is a very broad one, and it is impossible to cover it fully in one discussion, but it is hoped that further experience may be cited on this same topic, especially in reference to a cost system and to the best methods for use in small towns and villages.

Mr. Blanchard.

ARTHUR H. BLANCHARD, M. AM. SOC. C. E.—Mr. Farrington properly considers the work of maintaining bituminous surfaces and bituminous pavements under three heads: first, routine maintenance, being the continuous repair of small areas of a surface or pavement; second, re-applications of bituminous materials over practically the whole surface; third, reconstruction of the wearing course.

The second and third classes of maintenance may be accomplished by day labor or contract, or a combination thereof, the problems involved being usually identical with those of primary construction. The relative advantages of the general methods referred to and the plant equipment required have formed the subject-matter of several previous discussions before this Society.* The speaker will confine his discussion to the field of maintenance work first mentioned above.

In considering the equipment required to accomplish continuous maintenance of bituminous surfaces and bituminous pavements, it seems desirable to cite certain factors and principles which appear to be essentials of economical and satisfactory maintenance.

1.—Small failures of the wearing course, and the wearing away of the bituminous surface on comparatively small areas should be repaired immediately. Otherwise the rate of disintegration will be materially increased, the annual maintenance charge will be greater than necessary, and the surface will be unsatisfactory to the users of the highway.

2.—Continuous maintenance should be conducted so that the highway may be at once opened to traffic without injury resulting to the repaired sections. For the repair of potholes, ruts, and other holes or depressions, this implies the use of bituminous materials of much lower penetration than have ordinarily been used in many cases. If

* *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 25; Vol. LXXV, p. 548; and Vol. LXXVII, p. 171.

practicable, the same type and grade of bituminous material should be used for the surface application as was placed in the original construction. Mr. Blanchard.

3.—In order to accomplish satisfactory results the labor should be efficient and should be under the supervision of an engineer experienced in the construction and maintenance of all types of highways, and with all kinds of bituminous materials used in the area under his jurisdiction.

4.—The intimate relationship between the methods and materials used in construction and the character of the maintenance, in the case of bituminous surfaces and bituminous pavements, is such that, to ensure success, the construction and maintenance of highways in a unit of area, or a certain mileage, should be under the supervision of one engineer.

To accomplish continuous maintenance economically and efficiently under the foregoing conditions, the flying squadron, operated under the direction of an engineer in charge of construction and maintenance of highways in the area covered, appears to be the logical solution. The equipment of such a squadron will naturally depend on local conditions, such as the mileage of highways to be maintained, their relative location, the types of surfaces and pavements, the kinds of bituminous materials used, the mileage under guaranty, etc.

As an example of a definite problem in continuous maintenance, take a county or a division of a State where a considerable mileage of bituminous surfaces and bituminous pavements has been constructed. Granted a well-maintained system, the work to be accomplished by a flying squadron would consist, first, of routine repairs, including filling all holes, ruts, and other depressions with bituminous concrete, using a type of aggregate and bituminous material suitable to each case, and, second, applying bituminous materials to all areas which gave indication of being in such condition that they should be re-treated at once rather than wait until the whole surface required another application. It will be practicable in many cases for the flying squadron to repaint guard-rails and perform other routine repair work. Under such conditions, it is believed that the use of a motor truck properly equipped will prove most satisfactory. The suggestion to use a motor truck in repair work on highways is not novel, trucks having been recommended and used for this purpose for several years.

The equipment to be carried by the motor truck for the special repair work outlined should include the following machinery and tools: a rotary heater and pug mill mixer; two heating tanks; a surface heater; storage tanks and barrels for bituminous materials of different types and grades; storage capacity for small tools such as brushes, squeegees, tampers, cutters, pouring cans, irons, shovels, picks, and hoes; and storage capacity for paints for guard-rails, mineral aggregates, and road metal of several sizes. Although a storage capacity

Mr. Blanchard.

for mineral aggregates and road metal is called for in this equipment, it should be noted that only a few cubic feet of these materials will be carried, because the maintenance work performed will be confined to the repair of small patches. Usually, it will be practicable to reload a truck each day. The fixtures for the equipment described should be arranged so as to be readily removed, thus allowing the truck to be utilized for general hauling purposes. The equipment recommended should not be confounded with the elaborate equipment designed to cover all phases of repair work recommended by some engineers. The speaker believes there is danger in overloading a truck with accessories and thus rendering its operation uneconomical.

The equipment recommended herein could be carried by a 5-ton truck, capable of traveling 12 miles per hour, and having a gasoline storage capacity for a run of 100 miles. A clear body of 7 by 15 ft. would be available for the installation of the equipment. The cost of operation during an 8-hour day would vary from $10 to $20, covering wages of chauffeur, rent of garage, interest on first cost, maintenance charges, depreciation, insurance, tires, gasoline, oil, and grease. The speaker is indebted to Mr. Alfred F. Masury, Service Manager, The International Motor Company, for details relative to truck operation.

Mr. Fulweiler.

W. H. FULWEILER, ASSOC. M. AM. SOC. C. E. (by letter).—It is not economical to apply a bituminous material without some covering, as the greatest value of the treatment lies in the added wear given to the surface of the road by the mineral aggregate used as a covering, which the bituminous material merely serves to protect and retain in position. It is always economical, especially in the re-treatment of bituminous surfaces, to repair the surface before applying the bituminous treatment.

In patching, it is very important to see that the edge of the patch is cut back slightly, so that it not only forms a square edge for the new material, but that the material on the edge of the patch, which is invariably partly disintegrated by the action of the water, is removed.

The writer would like to inquire whether Mr. Farrington has any explanation for his statement that "Where tar is used in patching, more of it is required than with other materials."

As to the quantity of material to be applied on the surface, the writer's experience indicates that should it be desired to apply ½ gal. as a re-treatment on a bituminous surface, the best results would be obtained by applying not more than ¼ gal. at a time—with just sufficient covering to enable the wagon or motor truck to pass over the surface—then applying the remainder of the material and adding the stone used for covering. Where such a large quantity of material (½ gal.) is used in re-treatment work, it is advantageous to use stone

of a larger size, in fact the writer's best results have been obtained with a size commercially known as "$\frac{3}{4}$-in." Mr. Fulweiler.

The writer agrees with Mr. Farrington regarding the excellent results that may be obtained in patching with bituminous materials which are prepared so that they may be applied without heating, as this removes one of the serious difficulties in making a large number of small patches. Furthermore, such materials may be applied at almost any season of the year, and are much less affected by the presence of dust and moisture in the road surface.

In this day of definition and striving to attain accuracy in the use of technical phrases, the writer would like to inquire whether Mr. Farrington believes it to be good form to use a proprietary trade name in the way he has used the terms "Tarviating" and "Re-tarviating"?

In reference to the use of tar in re-treatments, the writer's experience has been that where the road is in good condition and an initial application of $\frac{1}{2}$ gal. per sq. yd. is made, that under favorable conditions, patching is all that is necessary during the second season, and about $\frac{1}{3}$ gal. per sq. yd. for the third season, followed by $\frac{1}{4}$ gal.; although, under many conditions, $\frac{1}{3}$ gal. every other season seems to be sufficient.

The writer does not agree with Mr. Farrington in reference to applying the covering to the bituminous material lightly at first. After a little experience it is very easy to estimate the proper quantity, and better results are obtained by putting on this correct quantity immediately. This saves trouble, annoyance to traffic, and prevents the formation of spots in the road, where, owing to the small quantity of covering, the road surface will pick up, especially under heavy steel-tired traffic. It is but fair to state that the writer is drawing purely on his own experience, which has been confined practically to a single type of material.

Slipperiness frequently results from the method of putting on the stone covering, as suggested by Mr. Farrington, as the application in small quantities tends to keep an excessive quantity of bitumen in the top of the road.

In connection with the description of the organization for surface treatment and re-treatment, the writer would be very glad to have an expression of opinion from Mr. Farrington as to the number of square yards per day treated by such organizations, assuming an average haul of 3 miles from the railroad station.

Mr. Farrington mentions a macadam binder, or the heaviest road oil to be used in re-shaping the surface of an old road. By macadam binder, does he mean a particular grade of bituminous material, or the usual stone screenings well watered and rolled?

In reference to maintenance work on screened gravel, the writer is in entire agreement with Mr. Farrington, that a fairly light grade

Mr. Fulweiler.

of bituminous material should be used on the first application, followed by a heavier grade, but finds it best to apply the heavier as soon as the light material has been absorbed into the surface. This same method has been used successfully on oyster-shell roads.

In re-surfacing old bituminous pavements, the writer's instinct would always be to advise scarifying, but the results of some work done during the past season would seem to indicate that, with care, it is possible to secure very good results by using crusher-run stone, free from dust, that will pass a 1½-in. screen, applying this as a covering over about ½ gal. of material, rolling thoroughly, applying about ⅓ gal. and covering with stone chips.

In the organization for re-surfacing, where a considerable amount of this work is to be done, the writer would like to call attention to a plan by which a very large amount of such work has been done on the State roads in Maryland during the past several years. Under this plan the State furnishes and applies the necessary stone covering, purchasing the stone and having it delivered in piles along the road-side in the early spring, when the price of teams is quite low. From a schedule prepared by the State engineers, showing the location of the roads to be treated, a price is agreed on, and a contract drawn up whereby the manufacturer of the material agrees, for a unit price per square yard, to sweep surfaces which have been previously treated with bituminous material, and also surfaces which have not been thus treated, and a unit price per gallon for applying the material, at the approximate rate shown on the schedule. In this contract for the past season, it was specified that all work should be completed before July 31st, with a penalty clause of $25 per day for every day that this time was exceeded. There was a further clause in which the company agreed to pay the State $25 per day for every day that it was delayed through breakdowns or the failure of material to arrive, and the State agreed to pay the company the same amount for every day that it delayed the application of the material through inability to cover it. This contract involved some thirty-four pieces of road in nine counties of the eastern shore of Maryland, amounting to about 118 miles, and containing 976 071 sq. yd. On this was applied 342 785 gal. of material, at a rate varying from ⅓ to ½ gal. per sq. yd., and averaging 0.366 gal. per sq. yd. This was covered with stone chips averaging 12 lb. per sq. yd.

Two motor trucks were used in this work, and they arrived about May 26th, although, owing to bad weather and some delay in organizing the gangs, work was not commenced until May 28th. One truck finished practically half of the work on July 18th, and the other finished on July 30th. The State maintained two gangs, of 12 men each, each under an inspector, for applying the stone chips, the company sweeping the roads and furnishing and applying the binder.

Mr. Fulweiler.

Practically this same form of contract had been in force during 1912, but during that year the work was not laid out according to schedule, and the trucks frequently had to make long jumps between the different pieces of work. This caused considerable loss of time, which was furthermore augmented by difficulty in securing proper labor. As the result of the experience of 1912, the work was laid out more systematically in 1913, and men composing the covering gang in one case were held throughout the season. The effect of having experienced men for covering is well brought out in Table 1 which summarizes the operations of the two years.

TABLE 1.—SUMMARY OF OPERATIONS FOR 1912 AND 1913.

	1912.	1913.
Sunday and holidays	21	20
Repairs and delays	22	6
Rain	5	9
Transit	34	18
Applying material	57	72
Total elapsed days	138	125
Percentage of days worked	66%	72%
Percentage of days material applied	41.5%	57.5%
Average No. of gallons applied per day	2 860	4 760
Average No. of square yards treated per day	8 230	13 550

The time is given in truck-days.

In 1913 the decrease in time lost in transit, repairs, and delays, is quite striking, as is the average increase in the quantity applied per day.

The writer believes that, in the long run, this plan, where there is a considerable mileage to be treated, is probably the most efficient and economical method of handling this maintenance work. One point, which is of considerable importance, is that, contrary to the case of an ordinary contractor, the company is vitally interested in securing the very best possible results from the use of its material, and therefore the inspector's duties are very much lightened, as there is no incentive to skimp the sweeping or other details in the application and then blame the quality of the material for the poor results which would inevitably ensue.

Mr. Sturdevant.

JAMES H. STURDEVANT, ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Farrington has well covered the subject of maintenance, without which any road system becomes an abomination instead of an improvement. Many times the writer has listened to tourists recounting a day's experience on the roads. They have expressed great indignation concerning some rough spots, but have not mentioned the many miles of smooth, easy-riding roads over which they have passed.

There are a few minor points to which the writer would like to call attention. These may seem to be trivial, but, if attended to, will result in ultimate satisfaction to the general public.

Mr. Sturdevant.

Patching.—In order to keep the surface of a road in smooth, proper condition, it should be under constant surveillance, and receive constant attention. As the surface becomes worn in places, and holes and ruts develop, they should be repaired at once, for if neglected they rapidly extend in size and depth under the action of each traveling vehicle. On bituminous surfaces, the best results are obtained, as stated by Mr. Farrington, if the asphaltic materials are first mixed with stone, gravel, or other suitable ingredients. This mixing can be done at any time, and in sufficient quantities to last for several months, for the weather will not cause the mixed material to deteriorate. The writer has used material which had been mixed during the previous summer and piled by the roadside, and has obtained as good results as with fresh materials.

In all patching work, the first requisite is to see that the surface to be repaired is well cleaned before new material is placed; also, in repairing holes and ruts, care must be taken not to use too much asphaltic material, and it is well not to have the new patch flush with the surface, for, under the action of the sun, the asphalt, whether light or heavy, will come to the surface. Then the patch will become sticky and is likely to be pulled off by heavy slow-going vehicles. To prevent this, more stone and fine material must be used as covering, and, if too much was used originally, a hump will develop which is as disagreeable as the original rut or hole. This is not as likely to occur when the material has been mixed before placing, as when the asphalt is placed first and then covered. Where the patching has been properly done—judging from the writer's experience and observation—it will last long after the original oil and surface have disappeared. This is true as to either light or heavy oils, or even asphaltic binders.

Re-oiling.—For re-treating bituminous pavements, the quantity of material to be used varies with individual roads. The original treatment should be in sufficient quantities to bind the road thoroughly and hold the stone in place, to prevent raveling; subsequent applications are for the purpose of providing a mat or cushion. For this purpose, the lighter oils are generally used, though excellent results, well worth the extra cost, are obtained with heavy binders. Considering, however, the lighter grades of oil, it is apparent that if used in excess they are not heavy enough to sustain the weight of traffic, and a rutted condition is sure to result. To avoid this, the application of oil should be uniform and of just sufficient depth to cover the surface, with no free oil remaining. After being covered, the surface should be watched closely, especially in warm weather, and as soon as the oil appears through the surface, more material should be added. In general with all bituminous surfaces, satisfactory results can only be obtained by keeping close watch of the road and repairing all defects as rapidly as they appear.

THE EFFECT OF SATURATION ON THE STRENGTH OF CONCRETE.

Discussion.*

By J. L. Van Ornum, M. Am. Soc. C. E.†

J. L. Van Ornum, M. Am. Soc. C. E. (by letter).—It is gratifying to note the several instances cited as showing the marked change in strength which results from saturating concrete which has been previously exposed in air. Undoubtedly there are many others, that have not been reported, which would indicate the same general tendency. Of course, the proportionate loss of strength occurring when an air-cured concrete is saturated would depend on a multiplicity of existing conditions, some of which have been referred to. One of these is the relatively large area of surface compared to volume in the test specimens, as noted by Mr. Worcester. It would seem probable, however, that the difference in loss of strength between the concrete in structures and that of the experiments would not be nearly as great as suggested by those comparative differences, because there is the partly compensating fact that structural members are generally exposed during construction to the drying effect of breezes and often to direct sunlight and a dry air, while the specimens were in a small closed room in which the air was comparatively moist. If, on the contrary, "the surface were kept wet for 7 days," it is believed that a large part of the loss on saturation would be avoided. Mr. Van Ornum.

With regard to the values of deformations and sets, which Professor Hatt assumes were withheld, it can only be stated that circumstances prevented their determination in connection with the tests reported. The only additional information pertinent to the subject, which can

* Continued from January, 1914, *Proceedings*.

† Author's closure.

Mr. Van Ornum.

be added, has reference to the suggestion of Mr. Worcester, that the actual strength of the specimens cured entirely in air "must have been rather lower than would naturally be expected of this quality of concrete." These cylindrical prisms averaged 1760 lb. per sq. in. Though this is about one-tenth less than the compressive strength that may be fairly expected of good laboratory specimens of these materials and proportions, they were actually somewhat stronger than the average of a large number of test prisms of similar concrete used in building construction and supposedly treated during curing in a way corresponding to that given to the material in the structures.

The writer hesitated to publish the paper at all, because of the many supplementary questions remaining for investigation, the determination of which is necessary for a complete understanding of the phenomena involved. Nevertheless, he concluded that the field of further research would be made more definite and available to others, if he presented the preliminary results already given. Of course, other percentage values will result from different experimental details, and the curve itself may be varied considerably in the same way. Yet it is believed that the broad, general fact of a significant loss in the strength of dry concrete when suddenly saturated and its gradual increase in strength to a final value considerably greater than the original one, when the saturation is prolonged, is a reality which should be definitely recognized in dealing with this important engineering material.

MEASUREMENT OF THE FLOW OF STREAMS BY APPROVED FORMS OF WEIRS WITH NEW FORMULAS AND DIAGRAMS.

Discussion.*

By G. E. P. Smith, M. Am. Soc. C. E.

Mr. Smith.

G. E. P. Smith, M. Am. Soc. C. E. (by letter).—The author's discussion of weirs is particularly timely, inasmuch as the necessity for the measurement of water by all water users is being felt at the present time. There are comparatively few irrigation projects in the Southwest where the water is not now delivered, nominally at least, by measure.

The author has rendered valuable service in collating the various masses of experimental data on the flow over suppressed weirs. There appears to be a general agreement among experimenters within 3%, though a divergence of results as high as 5% is not infrequent. Apparently, there is need of another set of experiments in which conditions and methods are defined much more rigorously than any thus far attempted. If an important new set is made in the future, doubtless the author will wish to amend his formulas. On account of the nature of the problem, no formulas can be accepted at the present time as final.

The Francis formula, a sort of average law, has been disintegrated into a multitude of formulas, each covering a limited range of conditions. This is in the interests of accuracy, and here the author has succeeded very well, but the writer cannot agree with him that it is in the interests of simplicity. Of course, the general use of accurately platted diagrams avoids the use of cumbersome tables, but errors in taking results from the diagrams can easily exceed the discrepancy between the author's and the Francis formulas.

* Continued from January, 1914, *Proceedings*.

Mr. Smith.

One assumption made at the outset of the paper is perhaps open to question. It is that the discharge is proportional to the length of crest. The influence of the side-walls on the discharge must be variable, depending on the material of which the walls are built and the character of the workmanship. The influence is comparatively slight for long crests, but of considerable importance in the case of short ones, such as are found in irrigation laterals and head-ditches. A serious difficulty in applying the author's method is the standardization of the side-walls. It is much simpler to standardize an edge than a wall.

It would seem to be unnecessary, too, to place the gauge so far up stream as is recommended. The object being to get back of the "surface curve," which depends mainly on the head, it is more reasonable to place the gauge at a distance back dependent on the head under ordinary or average conditions of the stream, say, at a distance equal to four times the head.

The writer formerly used the standard rectangular weir, but abandoned it gradually in favor of the Cippoletti weir, on account of the greater ease and simplicity of installing the latter. The Cippoletti weir requires much less construction than a suppressed weir, a pool being formed up stream in place of a flume. On one occasion the writer built and set an 18-in. weir, got a satisfactory reading and caught a train in 80 min. The Cippoletti weir discharge is proportional to the length, and a table of discharges is so simple that an engineer is not required to interpret it. Probably the greatest error in its use is in neglecting the velocity of approach, and this error can be minimized by providing an ample height of weir, and by applying the usual Francis correction. Furthermore, it would be possible to analyze the Cippoletti weir in a manner similar to the author's, and the subsequent use of the "approved" tables would result in the highest degree of accuracy possible with weirs.

Whatever doubt the writer had regarding the accuracy of the Cippoletti weir was set at rest by observing an exceedingly valuable set of experiments in the hydraulic laboratory of the University of Wisconsin. These tests were performed by senior students under the direction of Professor G. J. Davis. They indicated that:

1. The ratio, 1:4, is correct for the side slopes;
2. The coefficient, 3.37, is correct for crests more than 6 in. long;
3. The error of the formula will be less than 1%, if the head does not exceed 0.4 of the length of crest.

The restriction sometimes placed on the rectangular weir is that the head shall not exceed one-third the length of crest.

Mr. Smith.

There is one idea expressed in the paper to which exception should be taken. The proposition to establish one type of weir for universal use by legislation is debatable at least. Legislators are not engineers, and the fewer legal restraints thrown around the Profession the better it will be for the Profession. There are no laws fixing the power of the transit telescope, or the size of sewer pipe, or steel rail sections, nor are such laws wanted. The standard unit of measure should be fixed, as it is, but the method, never. Better methods will be found in the future, and should not be debarred from use in advance. There are several good ways to measure land, to measure electric current, and to measure water. The best method for a particular case depends on the surrounding conditions.

Utah has a law establishing standard cross-sections for the roads of the State. Is it possible that the southern counties and the northern counties require the same road crowning and the same shape of gutters? In Arizona roads are built variously of volcanic cinders, gravel, out-wash deposits, caliche, and sand; some roads are used almost wholly by automobiles, others by burros; some are in pine forests, others where the rainfall averages less than 3 in. per year; some withstand traffic principally, others rain and frost, others terrific winds. Surely no standard cross-sections are applicable here. Logan Waller Page, M. Am. Soc. C. E., states that "individual judgment is necessary" to determine the cross-sections of roads.

Instead of more standardization, perhaps more originality is needed. Engineers sometimes follow the well-beaten track when much could be gained by taking the cut-off—a statement which is worthy of the following illustration. For several years the writer had charge of a weir in a mountain canyon near Tucson. The discharge of the canyon varies from a small trickle in the dry months of the drier years to occasional floods of more than 1 000 sec-ft. It was quite as essential, perhaps more so, to determine the discharge of the years of minimum run-off as that of the infrequent maximum years. What was needed then, was an adjustable length of crest. Another consideration was the shape of the canyon; there were vertical rocks on the north side, at the foot of which ran the small flows, and a rising bouldery streambed from there to the south side. The weir crest, 65 ft. long, was designed to fit the canyon. For 5 ft. on the north side it was level, and the remaining 60 ft. had a slope upward of 1 in 15. Consequently, the small flows were concentrated over the short-level portion. The weir was built for one-third of what it would have cost with a crest of standard shape. The discharge formula for the weir is derived by using Francis' formula as a basis, and integrating separately for the triangular portion. The differential equation for the latter is

$$d\ Q = 3.33 \left(\frac{x}{15}\right)^{\frac{3}{2}} dx$$

Mr. Smith.

and the discharge for the entire cross-section is given by the equation,

$$Q = 16\tfrac{2}{3}\ H^{\frac{3}{2}} + 20\ H^{\frac{5}{2}}.$$

The equation was tabluated and also platted as a curve. Generally, the curve was used in working up the nilometer records.

There were errors, of course, due to neglect of the velocity of approach, and, probably, to submergence during extremely large floods. The influence of the former could have been approximated, but it was desired to have any possible error on the safe side. The action of the flow was such as to keep the up-stream side scoured out to a depth of from 1 to 2 ft. Records were kept for 9 years, during which time the nilometer box was submerged three times. The credit for the design of the weir is due to Professor S. M. Woodward, of the University of Iowa.

The writer, while traveling in the irrigated portion of Italy, saw many different methods of measuring water, among them various forms of weirs, submerged weirs, submerged orifices, and partly submerged orifices. It was interesting to observe that, in most cases, the method used was best fitted to the conditions of fall, discharge, accuracy desirable, and relative cost.

In the western part of the United States it is likely that a modification of the Venturi water meter will come into use to a considerable extent.

STORAGE TO BE PROVIDED IN IMPOUNDING RESERVOIRS FOR MUNICIPAL WATER SUPPLY.

Discussion.*

By F. B. Marsh, Assoc. M. Am. Soc. C. E.

F. B. Marsh, Assoc. M. Am. Soc. C. E. (by letter).—This paper bids fair to be the starting point for much future consideration of this hitherto intangible question of the proper storage to be provided in municipal impounding reservoirs. For this reason the writer wishes to call attention to a factor which, although of relatively minor importance, yet becomes worthy of consideration when a water-shed has been developed well toward the economic limit, as, for example, the Croton. Mr. Marsh.

In allowing for evaporation in a well-developed water-shed, the area of water surface should not strictly be taken as that with all the storage full, because such a condition obtains generally for only a few weeks during the year, and in many years not at all. Moreover, the tendency is for it to occur at a season when the evaporation from water surfaces is small. The maximum evaporation occurs during the summer, when, as a rule, the storage has been depleted and the water surface is, therefore, smaller.

Opinions will probably differ as to what should be taken as an average condition of the reservoirs, but for present Croton conditions, at least, it is probable that the water surface corresponding to a condition of reservoirs two-thirds full would be a fair assumption. Certainly it should not be less than one-half.

The fact that the area of water surface is a continually variable quantity has led the writer to prefer stating catchment areas in terms

*Continued from January, 1914, *Proceedings*.

Mr. Marsh. of the total area, land plus water, rather than land area only, as used by the author. The correction for evaporation can apparently be made as readily on one basis as the other, and it has always seemed to the writer more convenient and logical to use the gross area, and less likely to confuse those who may have occasion to make practical use of the figures.

The author's warning that actual records of an individual stream, taken without reference to other data, are likely to be seriously misleading, even if they cover a considerable period, is strongly exemplified by the Croton record, where the average flow for the 18 years from 1869 to 1886 was 346 000 000 gal. daily, while for the next 18 years, 1887 to 1904, it was 449 000 000 gal. daily.

PAINTING STRUCTURAL STEEL: THE PRESENT SITUATION.

Discussion.*

BY MESSRS. H. A. GARDNER, A. W. CARPENTER, MAXIMILIAN TOCH, R. D. COOMBS, LEWIS D. RIGHTS, AND W. E. BELCHER.

Mr. Gardner.

H. A. GARDNER,† ESQ.—In referring to the behavior of various pigment paints, Mr. Sabin states that "our knowledge of paints is as yet largely empirical." This may be true in so far as it concerns any attempt to promote the use of a lead pigment, which is highly unsuited for the protection of structural steel, but it is a matter of great pride to the paint industry of the United States to point out the developments in paint technology which have been recorded during the past 10 years. In probably no other industry have such rapid strides been made. The achievements of Committee D-1 of the American Society for Testing Materials are especially noteworthy. The studies and researches of its members are largely responsible for the present state of this industry, in which the manufacturing processes are now controlled by the application of scientific principles. This change has led to a general abandonment of the slap-dash, secret-process methods of mixing paint, which at one time existed.

Regardless of the progress that has been brought about through research and practical test, it is not uncommon to hear the phrase, "some thirty years ago", repeatedly used by the skeptic in referring to the old-time methods and materials of painting. To assert that there is but one paint or pigment that can be used for painting any and all kinds of structures, is like asserting that one brand of patent medicine should be used for the cure of any and all ills. In these modern days, it is the practice to design paints so that they will

* Continued from January, 1914, *Proceedings*.
† Assistant Director, The Inst. of Industrial Research, Washington, D. C.

Mr. Gardner.

properly meet special requirements. In no other way can the best results be obtained.

Unfortunately, Mr. Sabin's statements regarding the Havre de Grace Bridge tests are incorrect, and therefore misleading. In referring to the excellent results obtained with red lead paints, he states that the red lead used was 98% pure. The analyses made by the Department of Agriculture, at Washington, show that the red lead paints which gave good results varied widely in their composition. No. 6 paint consisted of 65% of red lead, the remainder of the pigment being made up of silica and other pigments. No. 10 contained 88% of true red lead and 10% of litharge. No. 11 contained approximately 95% of true red lead, the remainder consisting of litharge. Moreover, these three paints (the prime coats) were all made with different grades of oil and in different quantities. The oil in No. 6 which was present to the extent of 45%, had an ash content of 10.6, an iodine number of 140, and an acid value of 30. The oil in No. 10 was present to the extent of 30%, had an ash of 10, an iodine value of 157, and an acid value of 22. The oil in No. 11 was present to the extent of 23%, had an ash of 2.5, an iodine value of 163, and an acid number of 14. Paints 12, 14, and 16, which also gave excellent results in these tests when used at the normal spreading rate of 600 sq. ft. per gal., were composed of mixtures of red lead with such pigments as zinc oxide, China clay, gypsum, silica, asbestine, and carbon black.

It is hard to understand how any one can draw conclusions, from such a test, as to the protective value of different single pigments. The Havre de Grace Bridge tests have served a most excellent purpose in determining the relative value of various commercial brands of metal paints. These tests, however, cannot be cited as having contributed any definite knowledge relating to the effect of single-pigment paints as accelerators or preventives of corrosion. In fact, these tests were not designed for that purpose.

The only authoritative paint tests, to determine the efficiency of single pigments as preservers of iron and steel, which have ever been made, are those by the American Society for Testing Materials, at Atlantic City, N. J., in 1908. In these tests, which were made on a very extensive scale, the so-called rust inhibitive pigments proved the most satisfactory and received the highest ratings at every official inspection. Such pigments were either of the basic or the chromate type. The slightly soluble chromate pigments, such as zinc chromate, as Cushman had predicted, gave marked protection to the metal plates. The highly basic pigments, such as basic sulphate of lead, also gave excellent protection to the iron plates, to which they were applied as oil paints. Some of the most startling results of the test were recorded on test panels Nos. 34 and 36, and Nos. 9 and 10. Test panels No. 36 were coated with neutral chromate of lead. This pigment

Mr. Gardner.

is neutral and highly insoluble. It gave, therefore, only fair results. Test panels No. 34 were painted with basic chromate of lead. On account of the basic nature of this pigment (high litharge content), it gave marked protection to the metal sheets to which it was applied; in fact, this pigment was given a rating of practically 100% by every inspector at every annual inspection. At the end of 5 years' exposure to the sea air, this paint is still in perfect condition, and will probably give excellent protection to the iron plates for many years to come. Panels 9 were painted with that type of neutral red lead which Mr. Sabin claims to be a good protective paint. This neutral red lead paint at the end of 3 years' test gave very poor results on every plate to which it was applied. The surface whitened, chalked, and became covered with little rust spots. The neutral and inert nature of this red lead made it of no more value as a metal paint than ordinary clay. On plates No. 10 there was applied a red lead containing a considerable percentage of litharge. At the official inspection of the tests, this basic litharge red lead received a very high rating, and completely demonstrated its superiority over the neutral red leads.

If the engineer is to adopt red lead as a primer for structural steel, he should specify that the red lead used, if in dry form, should be mixed on the job in oil, or if in prepared mixed form, should be a red lead of inhibitive properties. In the speaker's opinion, it should contain not less than 80 or more than 90% of Pb_3O_4, the remainder being litharge. Most high-grade red lead will run between 82 and 90% of Pb_3O_4. The red lead used should be extremely fine; 99% should pass through a 200-mesh screen. It should contain not more than 0.5% of impurities of any type. Engineers who are responsible for the upkeep of steel bridges, railroad equipment, and similar structures on which red lead is used, are rapidly becoming convinced of the value of basic inhibitive red lead. Specifications issued by the Union Pacific and Southern Pacific Railroads, and the City of Pittsburgh, call for a pure red lead having a minimum of 85% of Pb_3O_4. Specifications of the Rock Island System, the Illinois Central Railroad, and the Yazoo and Mississippi Valley Railroad call for a minimum of 80% of Pb_3O_4. The Public Service Commission of the State of New York has also issued specifications for a red lead having a minimum of 85% of true red lead. This red lead will be mixed with iron oxide, silica, asbestine, and similar pigments, and made into prepared paints. These paints will be used on the new elevated and subway roads.

That thoroughly inhibitive pigments are necessary for the protection of steel cars is evident from the practical tests made at the Pullman shops in Chicago, where thousands of steel cars are produced annually. The following quotation from a paper on this subject, as prepared by the chief chemists of the Pullman Company, presented at a recent meeting of the Master Car and Locomotive Painters' As-

Mr. Gardner.

sociation is quite illuminating, in view of Mr. Sabin's statements regarding rust inhibitive paints:

"The pigment must be of such material that it will be inhibitive, or, in technical words, must be alkaline to a slight extent and positive electrolytically to the steel or preferably a combination of both those factors. The Pullman Company, through their laboratory, devised a very comprehensive and careful series of tests, taking into account all the above factors and many more of slightly less importance. All these tests have checked up remarkably well with outdoor exposure tests on steel panels."

As this reference indicates, rust inhibitive pigments of the basic type are being used widely for the protection of metal surfaces. For this purpose, there are many pigments which have proved quite as suitable as the best grade of red lead. Among these may be mentioned basic sulphate of lead (blue lead), zinc oxide, and the red and black forms of iron oxide. Prepared metal paints made from such pigments have proved highly efficient in test and in practice.

In summing up this discussion, the speaker wishes to impress on the engineer the necessity of using, as a priming paint for metal, one which will contain thoroughly inhibitive pigments, either of the basic or chromate type. Manufacturers of lead products may find that they can economically work up their off-color, low-grade, white lead for producing neutral red lead of 98% tetroxide content. Such a product, may possibly be used in the manufacture of rubber goods, glass, or pottery, but is entirely unsuited for application to steel. To recommend such an inert pigment for the protection of iron, shows either a total ignorance of the well-recognized principles of metal protection, or an absolute disregard for the principles of conservation. In the speaker's opinion, it is quite as criminal to recommend a worthless paint for use on the steelwork of a modern structure, as it would be to allow the use of structural steel which is physically imperfect. In either case the ultimate result would probably be the same.

Mr. Carpenter.

A. W. CARPENTER, M. AM. SOC. C. E.—In his brief and well-written paper, Mr. Sabin has given a great deal of very interesting information, from his point of view, on some of the newer theories and practices regarding oil paints for the protection of ferrous metals. He has used the opportunity to deprecate certain theories he does not himself accept, and devotes a large part of the paper to red lead, the paint pigment in which he is especially interested. He states that "when a new theory is offered, some of them [referring to paint chemists] make a great rejoicing over it without first finding out whether or not it agrees with the facts."

In spite of the speaker's sincere respect for Mr. Sabin's knowledge and experience, he is tempted to suggest that he is indulging in a little rejoicing himself over this new red lead theory, without offering much

Mr. Carpenter.

proof as to agreement with the facts. He states (1) that it is now known that the value of red lead depends on the quantity of true red lead it contains; (2) that the finer the red lead, the better it is; and (3) he suggests that red lead with more than 6% of litharge, when mixed with oil, will set in a day or so. This is evidently offered in opposition to another new theory which has been advanced, which is, that a certain proportion of litharge, at least in the form existing in the red lead as a result of the process of manufacture, is a benefit to the material as a paint pigment. The only evidence Mr. Sabin offers in support of his claims is the reference to the tests on the Havre de Grace Bridge, and this is not very satisfactory, as he does not state the litharge content of the two red leads used straight, and there might be some question as to the influence of the pulverized silicate on the third red lead mentioned. On the other hand, the only evidence offered in support of the theory that litharge is a valuable element in red lead, as far as the speaker knows, is the Atlantic City tests, in which ferrous plates coated with paint made with a red lead containing a proportion (stated to be about 12%) of litharge, were better protected after 5 years' exposure than similar plates coated with paint made with orange mineral, which contained practically no litharge.

The speaker's principal object in discussing this paper is to suggest that perhaps both these contradictory theories are wrong, or, at least, not worth the fuss that is being made over them. This suggestion is the result of a series of tests of samples of red lead of varying composition, as shown in Table 1.

TABLE 1.—TESTS OF RED LEAD FOR NEW YORK CENTRAL LINES BRIDGE ENGINEERS' COMMITTEE.

No. of sample.	Chemical Analysis.			Fineness.		Spreading Capacity of Paint.					
						24 lb. lead to 1 gal. oil.			30 lb. lead to 1 gal. oil.		
	True red lead. Percentage.	Litharge. Percentage.	Other elements, approximate percentage.	Relative fineness.	Weight per cubic inch, in grammes.	Square feet covered.	Relative percentage.	Working qualities.	Square feet covered.	Relative percentage.	Working qualities.
1	94.2	5.7	0.2	2	27	23	74	O. K.	30	79	O. K.
2	92.9	7.0	0.01	3	33.6	20	65	Covered poorly and brushed out hard.	29.5	77	O. K.
3	87.7	11.7	0.5	1	23	28	90	O. K.	33.5	88	O. K.
4	84.5	15.2	0.3	3	33.6	31	100	Mixed thin and sagged.	38	100	O. K.
5	80.6	19.1	0.3	1	23	20	65	Brushed out well but ran.	27	71	O. K.

Quantities for spreading tests: ¼ pint of oil to 12 oz. and 15 oz. of lead, respectively. Spreading tests made May 18th and 22d, 1911.

Mr. Carpenter.

This table shows the results of the examination and tests of five samples of red lead, each furnished by a different manufacturer. It shows the fineness of division, the chemical composition, and the spreading capacity when mixed with linseed oil in the usual paint proportions. It will be noted that the true red lead content ranges from 80.6 to 94.2% and that of litharge from 5.7 to 19.1 per cent. The fineness determination was made by the weight method, and is merely a comparative one based on the theory that the fineness of division of materials of equal specific gravity and similar structure of particles will vary inversely as the weight of equal volumes of the materials when equally packed. The weights given were determined by sifting the leads through a 20-mesh wire screen, placed at a fixed height above the measure of volume until the latter was filled, striking the material off flush with the top of the measure, and then weighing the contents. The lead with the lowest true red lead content (Sample 5) was found to be a tie with one other as the finest in division of all five leads; and the lead having next to the lowest true red lead content (Sample 4) was a tie with one other, the one with next to the highest true red lead content (Sample 2), as the coarsest. The other cases exhibit a similar lack of law of relation between true red lead content and fineness of division.

The paint mixtures for the spreading tests were made with open-kettle boiled linseed oil and no drier. They were applied to clean, galvanized, sheet-metal surfaces—well weathered and apparently all in the same condition—by one operator, on the same day, and under the same weather conditions, using a separate clean brush of one size and kind for each paint. The quantity of paint was small, but covered an appreciable area in each case, and the results with the two proportions of lead and oil will be noted as generally consistent. They show that one of the two coarsest leads (Sample 4), and the one having next to the lowest true red lead content, gave the greatest spreading; and one of the finest leads, which had the lowest true red lead content (Sample 5), gave the smallest spreading.

It seems safe to say that, if these tests are a correct indication, there is no definite relation between the fineness, the proportion of true red lead, and the spreading capacity of the pigment in oil, but that other elements control.

The foregoing determinations, of course, do not give any indication as to the durability of the respective leads in paint, nor their respective values for the protection of ferrous metals from corrosion. In the endeavor to determine these qualities, the leads were mixed with boiled linseed oil in the proportions of 20, 25, and 30 lb. of lead to 1 gal. of oil, and the resulting paint was applied, under three different conditions, in one coat each on steel plates 5 by 7 in. in

lateral dimensions. The paint was prepared by first pouring a small proportion of the oil over the full quantity of red lead and letting it stand over night. Next morning, the remainder of the required quantity of oil was added, and the whole was stirred thoroughly. Mr. Carpenter.

Three lots of paint, one for each proportion of 20, 25, and 30 lb. per gal. of oil, were thus mixed from each of the five samples of red lead, thus making fifteen lots. From each of these fifteen lots a steel plate was coated and properly marked for identification. Then from each lot, two small wide-mouthed bottles were partly filled. One of each of these bottles was allowed to stand open, without stirring, for a period of 2 weeks, at the end of which time the paint was stirred and applied to a steel plate in a single coat; in no case had the mixture set so that it could not be readily stirred and applied in a good coat, although in one or two cases the coats were quite thick. The paint in the second set of bottles was stirred every day for 2 weeks and was then applied to steel plates, except that one lot had set so that it could not be applied; that one was made from Sample 5 in the proportion of 30 lb. of lead to 1 gal. of oil; this sample contained the greatest proportion of litharge, 19.1 per cent.

After coating these plates, they were exposed to the atmosphere on the roof of an office building in New York City and left for 463 days, or 1 year and some 3 months. They were then brought indoors and examined with the following result:

The plates to which paint was applied immediately after preparation were in generally good condition. Those coated with 25 lb. to 1 gal., were in the best condition, although the coatings had changed color. There was no choice between the coatings with leads made by the different manufacturers. The 30-lb. per gallon coatings were too thick in some cases, and showed more breaks, with rust spots, than the 25-lb. per gallon coatings. The 20-lb. per gallon coatings showed the best color, probably due to the greater protection of the pigment by the oil.

The coatings with the mixtures which stood 2 weeks before application, in many cases were as good and had protected the steel as well as those applied immediately after preparation; in some cases it was evident that the mixtures had commenced to thicken or "set" at the time of application.

The coatings applied after the mixtures had been stirred daily for 2 weeks gave good protection, with two or three exceptions. They generally were not quite as good as those from the paints which stood 2 weeks without stirring, and the latter were not quite so good as those from the paint applied immediately after preparation. In several cases the paint had begun to thicken up or "set" when applied, but the results from these coatings were decidedly good.

Mr. Carpenter. In view of the foregoing there does not seem to be anything to choose between the different leads, as affecting the durability and protective qualities of paint coatings in which they are incorporated. For economical reasons, the choice would seem to lie with the one that spread the farthest, but there does not seem to be any way to predetermine the spreading capacity of paint made with any particular lot of red lead, from the fineness of division or litharge content of the lead, at least within the range exhibited by the samples tested.

It may be thought that the exposure tests were not long enough for comparative results. In this regard attention is called to the fact that the tests were made on single coats, and that the time was rather long for such.

It is not the intention to offer these tests as in any way conclusive, but simply as some definite determinations, as opposed to mere statements of opinion. It is hoped that others may take up the investigation, to the end that the facts may be established. It would seem to be a good field for investigation by the National Bureau of Standards.

Mr. Sabin's paper would lead one to think that red lead is the only good pigment for paint for preserving ferrous metals. Although it is undoubtedly one of the best of the practical pigments for use under many conditions, there are other conditions under which it is not satisfactory; and it is doubtful if its use in more than one coat is desirable on structural steel for ordinary exposure, owing to its cost, its susceptibility to deterioration in color and integrity in contact with gases, and its often objectionable color.

It may be very well argued that one or two under coatings of red lead paint will be generally improved by over coatings of paints with other and cheaper pigments, rather than additional coats of red lead. The speaker has also known of many instances in which oxides have made remarkable records for durability and protection in paint coatings applied directly to steel surfaces, and, he has a much higher regard for the value of certain iron oxides for use in structural steel paints than the author expresses for this class in general.

Mr. Toch. MAXIMILIAN TOCH, ASSOC. AM. SOC. C. E.—This paper can hardly be said to throw any new light on an old subject; an analysis of all that it contains can be summed up as a propaganda for an alleged new material known as red lead ground in oil, and sold in paste form.

Mr. Sabin's conclusions with reference to the condition of the paints on the Havre de Grace Bridge and the final report are incomplete. The report really describes as excellent nine paints, three of which are red lead; and one of these is a ready-mixed red lead containing, as he says, 15% of a pulverized silicate. Now, to be frank, such an indefinite term as "pulverized silicate" should not be used.

Mr. Toch.

The paint in question contained a substance known as aluminum silicate, but better known to engineers as ordinary American clay. The statement that 15% of the composition of this paint was clay is also misleading. Mr. Sabin, however, has corrected this by stating that the percentage of clay is nearer 25. The specific gravity of clay is a little greater than 2, the specific gravity of red lead is about 9. The volume of these two materials is such that the actual quantity of clay in this paint was nearly as much as that of red lead. In other words, 25 lb. of a good, clean clay has the same bulk as 85 lb. of red lead.

Now, what has the author proved? That the two pure red leads in these three results were only as good as the red lead which was mixed with clay, and, therefore, that clay, when mixed with red lead in moderate proportions, is just as good as red lead, for, after 6 years, there has been no difference in these three test plates. Then again, every one of these red leads was coated over with a carbon paint, and, if the test proves anything, it proves that the carbon paint was a perfect excluder of oxygen and water, and therefore no rust resulted.

The speaker has examined the report of the Havre de Grace Bridge committee very thoroughly, has been active on this committee to some extent, and has inspected these plates. Mr. Gardner has stated that among the paints which have turned out the best was that on Plate No. 12, and as nearly as can be determined from the report, that plate is the only one having two coats of paint, all the others having three coats; and the 600-sq. ft. spreading test is as good as the best. The speaker is not ashamed of this, in view of the fact that it was a paint invented by himself and made by his firm. Bearing out Mr. Gardner's statement with reference to the inhibitive quality of the basic paints, that on Plate No. 12, according to the published analyses, was the only one which was alkaline, due to the fact that the priming coat was a now fairly well known cement paint. The finishing coat was a carbon paint, and after 6 years these two coats are equal to the three coats of the others.

Four smokestacks for the power-house of Long Island City were painted in August, 1906, and are in as good condition to-day as they were 7 years ago. In that case three coats were applied, but the first was painted directly on rust, and that rust has never progressed sufficiently to scale the succeeding coats of paint.

The author has not even "damned by faint praise" any other material as a paint. On December 13th, 1913, the speaker examined very critically the test plates at Atlantic City which were painted in 1908 with single pigments, where, for instance, oxide of iron, red lead, graphite, etc., were applied without any subsequent protective coat, and he must take issue with Mr. Sabin, for the three red lead plates which are still on exhibition there are not as good as the three plates

Mr. Toch. covered with Prince's metallic brown, which is an oxide of iron; nor is the American orange mineral, which is a pure form of red lead, anywhere near as good as the sublimed blue lead. In fact, to be perfectly frank, the sublimed blue lead is far better than either red lead or orange mineral.

Allusion must be made to Mr. Sabin's statement: "one should not be disturbed by talk about 'newer paint oils'." The author did not mean "newer paint oils" when he put those words in quotation marks, but intended to refer to "newer paint materials," which was the subject of a lecture delivered by the speaker in London nearly 3 years ago, and the speaker is quite sure that Mr. Sabin is not so much against progress as this statement would indicate. Considerably more than 100 000 copies of that lecture were reprinted, and it has been quoted extensively both in Germany and in France, therefore, when Mr. Sabin pretends that there are no newer paint materials, the speaker is not inclined to take him seriously.

The speaker has always held the strong opinion that no man should take out of the common store any more than his allotted share. To him it is just as criminal to corner the wheat market and raise the price of bread as to take money out of the pockets of other people; there is this difference, however, the pickpocket can be prosecuted, but the man who raises the price of bread can not.

About 4 years ago, at a time when the crop of turpentine was normal, some men in the South cornered the market. Hundreds of thousands of gallons were stored, and none of it was sold until the price, which should have been about 45 cents, was raised to $1.13 per gal. The speaker very quietly cast about for a substitute for turpentine, and so did many others. There was one man, in the employ of the United States Navy, who showed much more courage than any admiral ever did in battle, when he wrote a specification for turpentine substitute for the United States Navy, and in one year reduced the purchases of turpentine in the Navy about 70 000 gal. A large number of other progressives did the same thing, with the result that to-day we can do without turpentine absolutely, and the price in its tumble shattered those who had raised it abnormally.

About 3 or 4 years ago, through the failure of the flaxseed crop in the United States and other countries, the price of linseed oil rose from 36 cents to $1 per gal. Although the speaker has never contended that he had found an oil which was just as good as linseed, he has proved that there are several which, in conjunction with linseed oil, make most excellent paint. If the author thinks there is nothing in the newer paint materials, let him ask the manufacturers of printing ink, linoleum, artificial leather, and also a number of paint manufacturers, whether Soya bean oil and Menhaden oil are not valuable assets to them to-day. A few months ago one of the largest manufacturers

of Menhaden oil stated that where he sold one barrel to the manufacturers of paint and linoleum 10 years ago, he is selling a thousand barrels to-day. In the speaker's lecture on fish oil he pointed out that many of the failures were caused by the ignorance of the men who made the tests. On any price list of fish oils to-day will be found whale oil, porpoise oil, and seal oil, under the heading of fish oils, and it was the speaker who pointed out to the paint industry that these are animal oils and not fish oils, and, further, that a fish oil, to be suitable for paint material, had to possess certain constants, otherwise it would be useless. Mr. Toch.

In 1896 5 gal. of China wood oil came to the United States. As far as known, it was the only China wood oil imported that year, and the speaker received those 5 gal. During the year ending October 31st, 1913, 5 400 000 gal. of China wood oil were consumed in the United States. This oil, before it was understood, had a very bad reputation as an adulterant and an undesirable paint material. When one talks about adulterants one is treading on very thin ice. Everybody is familiar with the high-priced Epicurean dish known as terrapin. To serve terrapin at $3 per microscopic portion is considered in high society a great feat, and yet, 150 years ago, when a good slave was sold in Maryland, the agreement generally made was that the slave must not be fed on terrapin, for at that time it was considered hardly good enough food for dogs. If China clay, which is the pulverized silicate mentioned by the author, were equal in price to red lead, a feature would be made of its use instead of a secret.

This paper tends to show that there is a new material on the market known as red lead ground in paste form, which can be very easily thinned and made ready for use. Pure red lead, ground in pure linseed oil, in paste form, has been known for many years, and, what is more, the author knows it has been known, because orange mineral, which is a pure form of red lead, has been used by color grinders as far back as the speaker can remember. The speaker made ready-mixed red lead more than 20 years ago, and made it successfully; and it remained in its ready-to-use form. He has no quarrel with red lead, because he thinks it is a very good material. It is not better than sublimed blue lead, nor is it better than certain forms of oxide of iron. It is certainly very much dearer than any other paint, and, on account of its great weight, it is harder to apply than a lighter one; it does not stop progressive oxidation, nor is it a fit material for use on steel which is to be bedded in concrete, not because of the red lead, but because of the oil, which is readily saponified.

Everybody must admit that in some places red lead is a most excellent protective paint, but in other places it does not give such a good account of itself. Then again, every paint chemist knows that there are some red leads that contain nearly 1% of caustic soda, which

Mr. Toch. is quite sufficient to destroy a paint when it comes in contact with water, and all know that the red lead which can be ground in paste form and remain plastic is not the red lead that has been used heretofore, which contains litharge, and the old litharge red lead paint should not now be condemned because it forms a cementitious material.

As a paint under water, red lead is sometimes good and sometimes bad, depending, of course, on whether or not it has been made by the nitrite of soda process.

A large quantity of red lead was used on the steel of the locks of the Panama Canal as a priming paint, three coats being applied in many places. When submerged in the lake water, the red lead turned blue, owing to the action of the sulphur gases on the lead, and the paint was in many places entirely destroyed. Whether this was due to the fact that it contained a small percentage of free caustic soda and thereby became soluble in water, or whether the decaying organic matter destroyed it, amounts to the same thing. Preliminary tests, however, may have demonstrated these defects.

The speaker has at all times stood for fairness and the exact representation of facts with regard to paint materials. He has spoken well of all those materials which his judgment and experience have taught him were good. He has even had the temerity to talk well of his own paints whenever he has had the chance, for the world is large enough to support all, and to give every one a share. He is glad of the opportunity to state that he and Mr. Sabin have been friends for many years, and he respects him highly. In differing in opinion with him, he is simply breaking a lance in the interest of paint science. The author is a man who is well equipped, and has had a long and varied experience which entitles him to the right to talk, but the speaker agrees with the poet Goethe, *"Der Mensch verhoent was er nicht versteht"*, which, translated into good "American", means "A man is down on a thing when he is not up on it".

Mr. Coombs. R. D. Coombs, M. Am. Soc. C. E.—The manner in which paint is ordinarily applied in commercial practice is so irregular and faulty as to render any direct comparison inaccurate. The painting, as usually done on structural steelwork, is about the poorest job on the entire construction. As most erecting engineers know, the work of painting is disliked by the higher priced men—the iron-workers. Instead of having the work done by a $4 or $5 iron-worker, it is done by a $2 to $3 steel painter or apprentice, and it is frequently a very poor sample of painting. Again, in the entire painting, the shop coat would seem to be the thing which can most easily produce a poor result.

The average paint used in the shop is a relatively cheap material, costing about one-half as much as a good field coat, and it is frequently put on by the cheapest labor in the shop, and more frequently it is put on very badly. Now, it would appear reasonable to expect that

Mr. Coombs.

a poor shop coat over an imperfectly cleaned surface would have a very great bearing on the final net result of the work. Thus, if a $0.60 paint is put on in the shop as badly as is frequently the case, and then a $1.25 paint is used in the field, it seems open to question how much of the result of the final painting is chargeable to the shop coat and how much to the field coat.

Referring to the matter of red lead paint as practically applied—not as a laboratory test, but as done in the field—the question arises, how many pounds of red lead to a gallon of oil should one expect low-grade painters to use successfully. There are in existence a number of specifications, issued by individuals and corporations of high standing, calling for 33 lb. of lead to 1 gal. of oil. On a rather important piece of construction, in the vicinity of New York City, the master painter, who was in the employ of the company and had no object whatever in cheapening the work, reported that he could not put on as much, unless he was allowed to use a trowel. This may have been an exaggeration, but it is the speaker's recollection that about 22 lb. was as much as the men found they could work with to advantage.

The speaker does not wish to convey the impression that the painting in the field is a much better piece of work that that done in the shop, but that the painting, either in the shop or in the field, as usually done, is not a good job. Further, the manufacturer alone is not to blame, but also the owner and the engineer. It is simply a bad practice which has become very common, and for which all concerned are at fault. Reference is not made particularly to red lead paint, but to all paints.

There seems to be some tendency on the part of the manufacturer to regard the multitude of paints now specified as a senseless nuisance, and—it must be admitted—with perhaps some justification, from his standpoint. However, having recovered from his chagrin at the receipt of an order embodying another change in paint from the kinds in immediate use in the shop, and after faithfully incorporating the proper instructions in the shop orders, he often takes no further interest in the matter. The paint question is now up to the shop foreman, whose theories thereon are often in need of expurgation as well as elaboration. To the minds of many shopmen, who take a real pride in doing good shop work, any old paint of the specified color is good enough.

Turning now to the paint man, it is difficult to understand how he can escape responsibility for at least part of the skepticism of the manufacturer, engineer, and owner, as many paint salesmen rather permit the impression to get abroad that the paint used by their competitors will eat the steel rather than protect it.

The private owner is not so much to blame, as he is neither an engineer nor a paint expert. Those corporate owners, however, having engineering departments, whose duty it is to conserve their construction interests, can hardly be absolved from blame for careless work.

Mr. Coombs. The speaker is unwilling, although able, to specify definite instances, in which a cheaper grade of paint than that specified has been used, or in which either, or both, the shop and the field painting have been very badly done. Painting in wet or freezing weather, the use of liberal quantities of "thinners" and benzine, painting over scale, rust, cinders, mud, etc., and the omission of paint, are not such rare occurrences as optimists would have us believe.

It would seem that it is about time for a reformation in the methods used in painting. Not so much in relation to the work done under efficient inspection as in the great bulk of work included in small contracts throughout the country, which are either poorly inspected or not at all. Where paint is really needed, it is usually badly needed; and, unfortunately, the work on which the future maintenance will be inadequate is just the work on which the original inspection and superintendence is inadequate.

It is the speaker's opinion that, in a great many cases, particularly for interior steel beams encased in concrete, no field paint whatever is necessary, and that the expense of painting such members would more properly be expended in the better painting of the members which really need it. Further—although it may seem contradictory to the previous remarks—better results might often be obtained by using a $5 man and $1 paint, than a $1 man and $5 paint.

As a result of some years of experience with a class of construction in which there are very thin members subject to an extreme and variable exposure, the importance of a revision in the common attitude toward the paint question appears to be of considerable importance. Such work may be regarded as an accelerated test, and as developing in a few years what may be expected in a longer period in heavier material, under incompetent supervision.

The speaker would like to ask Mr. Rights what he thinks the average price of shop paint is throughout the country, that is, considering the average of the total number of shops, not the average of the total tonnage.

Mr. Rights. Lewis D. Rights, M. Am. Soc. C. E.—The speaker, as a member of the American Society for Testing Materials, has attended the conventions at Atlantic City, has inspected the paint fence, and has listened to discussions regarding the values of inhibitors and stimulators. He has followed Mr. Sabin's paper and the discussions with a great deal of interest, with the hope that something would be brought out to help to clear up the situation, from the standpoint of one of the parties who is as much interested as any of the rest, if not more so. He refers to the bridge and structural manufacturer, who has the responsibility for the application of the paint, both in the shop and in the field, and is therefore a very important link between the paint manufacturer and the engineer and owner.

Mr. Rights.

It may not be out of place to mention the conditions under which painting is done at the shops of the structural and bridge manufacturers. So far as the speaker knows, very few of the bridge shops have any adequate facilities for doing their painting inside a building, where the work can be done regardless of wet or freezing weather. Although it is true that during the most severe winter conditions painting is done occasionally in the finishing end of the shop, facilities there are so cramped that the quantity of painting done under cover may be said to be almost negligible. It is safe to say that practically all the structural steel painting is done in the open.

Some years ago, the owners of one of the largest shops carefully considered plans for covering their shipping yards and protecting them so that painting could be done at all times. The item of expense, however, was such that it was decided that the condition of the business would not warrant increasing the cost of painting to the owners.

The bureaus which inspect a large proportion of the fabricated steelwork have a rule that the finished material must not be painted until their men have had an opportunity to go over it. Frequently, it takes an inspector several days to cover the shops in his vicinity, and this means that the steel must sometimes lie in the open for a day or so before it can be painted. Now, considering that painting cannot be done in either wet or freezing weather, nor can it be done until the work is inspected, it will easily be seen that the time allowed for doing the painting is very much reduced, and therefore, of necessity, the application of the paint at the shop must be a somewhat hurried job. In general, the class of labor doing the shop painting is fully as good as that employed in the other details of manufacture, and considerable care is exercised in endeavoring to see that all parts of the pieces are evenly covered.

In connection with the erection of structural steel, it has become the practice of many of the bridge manufacturers to sublet the painting to men who make a specialty of work of this class. It has been found that bridge erectors do not relish handling a paint brush, and better results have been secured with specially trained men. As the manufacturers are interested in producing a high grade of work, it has become the custom for them to buy the paint and ship it to the job in unbroken packages. It is then sold to the painting sub-contractor at an agreed price per gallon, and the work of applying the paint is inspected either by the owners' inspectors or by some one appointed by the bridge manufacturer.

The speaker would like to state here that the bridge manufacturer is not in favor of cheap paint. The fact of the matter is that he would rather put on a good paint, provided the cost of this good paint has been properly covered by the specification, and figured in his original bid. It will easily be seen that the more work the bridge manu-

Mr. Rights. facturer can put into a job, the greater will be his percentage of profit, and that, in addition, he will produce a more sightly structure. The bridge manufacturer carries at his shop several lines of standard paints, which are probably as good as can be bought under ordinary specifications, such as red lead, white lead, iron oxide, and some form of carbon or graphite. He is entirely willing to apply the best of these, as called for, or to provide a better paint, if required. What he most desires, however, is that the discussions which have been going on among engineers for the last few years will produce something in the way of standard kinds of paint suitable for each class of work. As matters now stand, it would seem that almost every engineer was working out his own theories of inhibition and stimulation, and that each one had a different variety of paint. Of necessity, the bridge manufacturer must order a somewhat larger quantity of paint than is actually required for each particular structure, with the result that the paint shop has the appearance of a medicine shelf, containing left-overs, each one strongly advocated by one individual engineer, and strongly condemned by all the rest of them. These left-overs will not remain fit for use very long, and are frequently a total loss to the manufacturer.

Years ago, a similar condition applied to specifications regarding the quality of structural steel. To-day, the manufacturer and the engineer have been able to get together, so that the same grade of structural steel is used for railway and highway bridges, buildings, and cars, and when the total tonnage is considered, the special-grade steel is a small factor. Cannot the paint manufacturers and the engineers get together on some such broad basis, and settle on paints which will be serviceable to the owner, without undue cost, which can be readily applied by the manufacturer, and which will fit 90% of the steel structures. "'Tis a consummation devoutly to be wished".

Mr. Belcher. W. E. Belcher, M. Am. Soc. C. E. (by letter).—This subject is certain to hold the attention of a large proportion of the members of the Society, for all are looking for more information. The writer, however, confesses to a feeling of disappointment in reading the paper, particularly in regard to the very small number of paint materials selected by the author for consideration, and also because of his failure to cite from his own wide experience definite records of paint performances from which engineers might be assisted in forming their own conclusions.

The writer would like to add the following random notes from his experience:

For several years a red lead paint was always specified by him for structural steelwork for buildings, following the example of many

railroad and Government specifications. When inspecting the work done under practical shop conditions, the paint was found to be more or less unsatisfactory. There was a decided tendency for the formation of a hard sediment at the bottom of the paint bucket, and ordinary paint laborers never stirred the paint with sufficient frequency to obtain a uniform coat; this would upset fine calculation as to the number of pounds of lead per gallon of oil. There are on hand in most bridge shops several kinds of red paint which can hardly be distinguished from one another immediately after application, and might easily be substituted for one another—unintentionally perhaps—without subsequent detection. The writer has seen on detailed shop drawings the paint note, "One Coat Red," though the original specification had been quite elaborate. If specifications could be reduced to this simple form there would be no difficulty in getting what is called for. Another point which seems detrimental to the use of red lead is the fact that its color soon becomes dull after exposure, without regard to the number of coats applied. Mr. Belcher.

The writer has always been prejudiced against graphite paints, on account of their extreme thinness and also because of the very conflicting arguments advanced by the manufacturers of the pure pulverized graphite paint, on one hand, and those of the mixed silica and graphite, on the other. A specification calling for Prince's mineral and for iron oxide to which graphite was added in small quantity for smoothness and color, was tried out with good results, and has since been followed. It overcomes very largely the objections above offered to red lead, and has generally good lasting qualities.

The preparation of a ground red lead paste mixed in oil would not appear to be entirely new, as one of the large paint manufacturers in Chicago submitted to the writer about three years ago a preparation called "Liquid Red Lead." This was a concentrated red lead paste to which, if memory serves correctly, a small quantity of silica was added, which assisted in an effective way against sedimentation.

This material was submitted in connection with a study of the subject of gas-holder paint. One manufacturer, submitting samples at that time, offered "Special Gas-Holder Red" which was recommended to fill every possible requirement, although the description of its manufacture was very vague. Investigation disclosed the fact that the manufacturers were as little certain of the desired ingredients of a gas-holder paint as the writer was, and, consequently, they put in a little of everything, including old house-paints, surplus paint stock, kettle scrapings, paint skins, etc., with enough red to color the mixture.

The writer is a firm believer in the theories of Messrs. Cushman and Gardner in regard to the corrosion of iron and steel; at the same time he must agree fully with Mr. Sabin that it is practically impos-

Mr. Belcher.

sible for an engineer to use them in their present state as a guide for intelligent selection of a paint material. Has any manufacturer or manufacturer's representative ever been forced to admit that his particular combination of oils and pigments has been in any way discredited by these theories and experiments? The author's remarks regarding lampblack illustrate this point. We have learned that lampblack is in itself injurious. The manufacturer then states that he has ground it in a certain way which changes its action entirely.

The science of engineering is largely empirical, based on observations and experiments. The present discussion in regard to painting structural steel emphasizes the incompleteness of our record of experiments in this particular branch of the science. In the present situation, our rules are still in the nature of theories and deductions from limited personal experience.

STRESSES IN WEDGE-SHAPED REINFORCED CONCRETE BEAMS.

Discussion.*

BY MESSRS. L. H. NISHKIAN AND WILLIAM CAIN.

Mr. Nishkian.

L. H. NISHKIAN, ASSOC. M. AM. SOC. C. E. (by letter).—On page 2083† the author computes the shear in section *N I*, Fig. 4. An important function of the inclined bar is to relieve the shearing stresses in section *N I*, but the author does not take into consideration the vertical component of the stress in the inclined bar. In order to have equilibrium of all the vertical forces acting on that portion of the base to the right section *N I*, the vertical component of the stress at section *N I* in the inclined bar should be deducted from the total vertical load, 18 333 lb., and the remainder will be the shear in the concrete in section *N I*.

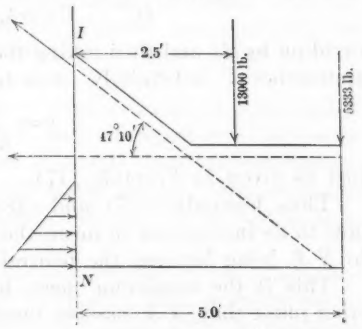

FIG. 12.

The sum of the vertical components, per foot of width of the stresses in the inclined bars, is

$$17\,750 \times 0.765 \times \frac{3}{2} \times \sin.\ 43°\ 10' = 14\,000 \text{ lb.}$$

and

$$18\,333 - 14\,000 = 4\,333 \text{ lb.}$$

Therefore the maximum shear in section *N I* is $47.6 \times \frac{4\,333}{18\,333} = 11.2$ lb. per sq. in. instead of 47.6 lb. per sq. in.

*Continued from January, 1914, *Proceedings*.
†*Proceedings*, Am. Soc. C. E., for November, 1913.

Mr. Cain. WILLIAM CAIN, M. AM. SOC. C. E. (by letter).—The writer would like to make a correction as to the meaning of v in Formulas (17) and (18), as others besides Mr. Janni* may inquire the reason for the statement that "The unit stress, v, acts parallel to $N\ N'''$". The statement is incorrect; v, in Formulas (17) and (18), is the unit shear on any plane, lying between O and the steel bars, perpendicular to $N\ I$.

Thus, suppose such a plane drawn in Fig. 8 and marked $A\ A'$ (A lying in $N\ I$, A' in $N'\ I'$), then since the section, $N\ I$, was taken parallel to the direction of the loads, at a point, A, where the bending stress is supposed to be zero, there is shear only on the plane, $N\ I$, and consequently a shear of equal intensity, v, on a plane, $A\ A'$, at right angles to $I\ N$, by a well-known theorem. The total shear on the plane, $A\ A' = v\ b\ dx$.

For equilibrium, the algebraic sum of the components perpendicular to $I\ N$, of the forces acting on $N\ A\ A'\ N$ must be zero. Therefore

$$(C' - C)\ \cos.\beta = v\ b\ dx,$$

which is the same as the equation just above (17). Hence, substituting this value in the equation derived just before the last, or in,

$$(C' - C)\ \cos.\beta\ D\ G = V'\ dx,$$

dividing by dx and then taking the limit, as dx approaches zero and V' approaches V indefinitely, it is found that,

$$v = \frac{V}{b\ \overline{D\ G}}$$

just as given in Formula (17).

Thus Formulas (17) and (18) are unchanged in form, but v is now to be interpreted to mean the unit shear on a plane perpendicular to $N\ I$, lying between the neutral axis and the steel.

This is the maximum shear, being greater than the shear on any other plane than $A\ A'$ passing through A; hence it is of special interest to the designer.

* In his discussion, *Proceedings*, Am. Soc. C. E., January, 1914, p. 239.

A STUDY OF ECONOMIC CONDUIT LOCATION.

Discussion.*

By Messrs. H. Hawgood and M. F. Stein.

Mr. Hawgood.

H. Hawgood, M. Am. Soc. C. E. (by letter).—The location of conduits for irrigation and power purposes should receive the same study as that for a railroad. Both are transportation problems, and the economic value of distance and rate of gradient are relatively as important in the one enterprise as in the other. Their importance in railroad transportation is fully recognized.

Mr. Hickok's paper is the outcome of studies made by him, under the writer's instruction, in connection with a Southern California project. His treatment of the subject is simple, and his conclusions are logical. The unit costs used in the paper are not fully endorsed by the writer, but, inasmuch as they are introduced for exemplification purposes only, they are not debatable.

In arriving at methods of comparing the economic values of alternative locations, the fact should not be overlooked that, however satisfactory the mathematical treatment, the conclusions must be tempered by personal judgment of the risks to which the local environments subject the alternative locations. Experience has shown that the risk of interruption of service is far less for tunnels than for hillside conduits, and weight is to be given to this and other working experiences in making a final selection of routes.

Mr. Hickok does not credit tunnels with any saving in seepage. Seepage from a water channel is governed, not only by the nature of the channel lining, but by that of the material on which the lining rests. No water would pass through a sieve set in impervious material. The sides and bottom of a rock tunnel may not be, and rarely are, entirely impervious, yet their opposition to percolation is of suffi-

* This discussion (of the paper by C. E. Hickok, Assoc. M. Am. Soc. C. E., published in December, 1913, *Proceedings*, but not presented at any meeting) is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Hawgood.

cient magnitude to aid materially the lining proper, and in most cases to reduce seepage to a negligible quantity.

In his graphical representation of results, the author uses a diagonal line for each combination of the costs of two structures. He gives seven different structures; taken in pairs, twenty-one combinations are possible. Twenty-one diagonals, with their legends, would be found to be confusing and impracticable of application. It might also, and probably would, be found convenient to add other types of structures, which would call for a considerable increase in the number of diagonals.

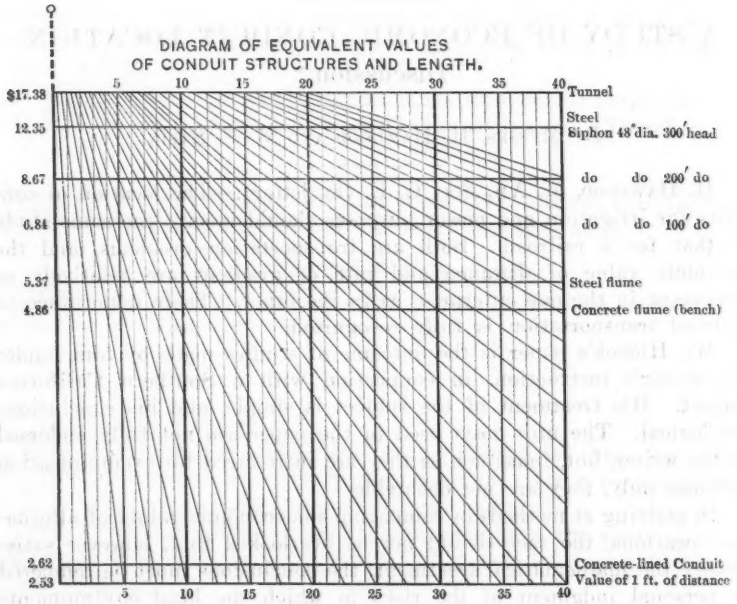

FIG. 3.

The writer suggests Fig. 3 as a more convenient form of diagram and as covering all phases of the subject. The radiating lines permit finding the equivalent distance, or type of structure, in terms of length of any other type of structure. The horizontal lines, each representing a particular type of structure, are spaced so that their distances apart vertically bear the same ratio one to the other as their respective unit costs. To exemplify the use of the diagram, assume that, of two alternative routes, Route No. 1 has 200 ft. more tunnel and Route No. 2 has 1 500 ft. more lined conduit and 300 ft. greater length of line. Find Vertical 3 on the base line representing the economic value of 1 ft. of distance; trace the radial thence up to the concrete-

lined conduit line, and read 289 ft.; add this to the 1 500 ft., giving 1 789 ft., the virtual length of Route No. 2 expressed in terms of concrete-lined conduit. Then find 2 on the tunnel line (top of Fig. 3), trace the radial down to the lined conduit line, and read 1 324 ft., which is the virtual length of Route No. 2 expressed in terms of lined conduit. A comparison of this value with that of 1 789 ft. for Route No. 2, decides in favor of Route No. 1. Mr. Hawgood.

M. F. STEIN, ASSOC. M. AM. SOC. C. E. (by letter).—Referring to Fig. 1, the writer notices that in the "Cement-lined Canal," "Concrete Flume," and "Tunnel" sections, the author has used a thickness of concrete of 3 in. It would seem, from the writer's experience and observation, that though this thickness may be theoretically sufficient to withstand the water pressure, it may not give a sufficient factor of safety for various contingencies which cannot be calculated. It is generally difficult to obtain water-tight construction with a thin wall, using the customary type of labor and superintendence in mixing and placing the concrete, and frost action may prove destructive in a cold climate, especially in the event of seepage through the concrete. A thin section, furthermore, provides little safety against cracking, should there be any unequal settlement. These points would apply with less force in a warm and arid region, but the author does not limit his discussion to such conditions. Mr. Stein.

As regards the tunnel lining, though this may be sufficient for very firm rock, where it is only desirable to obtain a smooth surface, for hydraulic reasons, it would not offer much resistance to the rock movements, shelling, and thrusts experienced in limestone, shale, or clay formations. This is exemplified in the recent failure of the Montreal conduit, under an apparent pressure much less than might be expected in certain kinds of rock, even though the minimum thickness of concrete was 8 in.

Although these arguments affect the diagram (Fig. 2) to some extent, they have, in the writer's opinion, a more important significance. Papers and discussions in the *Proceedings* are widely copied by engineering periodicals, and any diagrams, especially if dimensioned, are taken at face value by many engineers, outside of the Society, some of whom, by training and experience, are incapable of exercising proper discrimination. To such, the sections of Fig. 1 would make an especial appeal, owing to their apparent economy and simplicity, and might be applied without regard to their suitability to conditions which are not those met in average practice.

Relative to this, the writer recalls the failure of a small dam, about 15 ft. high, the design of which was copied from a textbook illustration of a well-known high arch dam, all dimensions being reproduced *pro rata,* with very illogical and inadequate results, further accentuated by the fact that though the original was built in rock, the copy rested on clay.

CONCRETE BRIDGES: SOME IMPORTANT FEATURES IN THEIR DESIGN.

Discussion.*

By A. W. Buel, M. Am. Soc. C. E.

A. W. Buel, M. Am. Soc. C. E. (by letter).—Mr. Gregory, Mr. Janni, and others have brought out most of the points involved, but there remains one of vital importance as affecting the comparison of the hinged and fixed-arch rib as made by the authors. Although they have used the proper form for their hinged ring, their fixed ring is neither correct nor economical; and, therefore, is not a fair comparison. Being segmental, it is subject to great moments at the springing line, as the ring does not conform to any pressure line for any practical conditions. Mr. Buel.

The only economic justifications for the three-hinged ring are difficult foundation conditions and a rise of less than one-sixth of the span with a possible yielding of the abutments.

The authors exaggerate the difficulty of computing the fixed arch, for, by systematizing and tabulating the work, it is quite possible to make the computations in 2 days or less. Moreover, it does not seem to be good engineering practice, nor creditable to the industry of the Profession, to advocate a design because it may save a few hours or even a few days of work for the designer. This is aggravated when there is room for the suspicion that any such saving in the designer's time and energy is largely due to his unfamiliarity with fixed-arch computations.

The advantages of the ribbed ring have been demonstrated and advocated† by the writer in designs worked out in 1899 and 1901.

THE DEPRECIATION OF PUBLIC UTILITY PROPERTIES AS AFFECTING THEIR VALUATION AND FAIR RETURN.

Discussion.*

By Messrs. Charles Rufus Harte, W. Kiersted, and George B. Stone.

Mr. Harte.

Charles Rufus Harte, M. Am. Soc. C. E.—Papers such as Mr. Alvord's, which by stimulating discussion tend to spread a broader knowledge of the important subject of valuation, are particularly valuable at this time when the situation seems not unlike that which led the old New Englander, not in sympathy with the party then in power at Washington, to add to his prayer for Divine guidance for the then President the earnest statement "Thou knowest, Lord, he needs it." At the same time, it would seem not entirely out of place here to raise the question whether, in the treatment of the subject, many of us are not beclouding the facts by analyses and discussions which are too academic.

The author's definition of "depreciation" includes four widely diverse items of loss of value:

1.—Organic depreciation—the loss of value because of wear of the substance of the elements which make up the machinery or plant—begins with the life of the plant and continues practically uniform to the end. Plotted in terms of time and loss, it is very close to a straight line.

2.—Functional depreciation—the loss of value because elements of the plant get out of correlation—begins with the life of the plant, and, particularly if not met by proper maintenance, accelerates very rapidly until near the break-down point, when it checks and then con-

*Continued from January, 1914, *Proceedings*.

Mr. Harte.

tinues slowly to the end. Proper maintenance brings back conditions, but not quite to what they were at the previous take up, so that, plotted in terms of time and loss, functional depreciation appears as a saw-toothed curve.

3.—Obsolescence—the loss of value because the product of the plant no longer meets market requirements as to character—may attack a property at any time, or may not occur at all. Occurring, it may progress with great rapidity; it may progress slowly; or it may progress, halt, and progress again; so that its curve, in terms of time and loss, may be of almost any form. A striking instance of acute obsolescence is that which, almost over night, changed the cable traction system of the Broadway street-car line in New York City from the latest word in traction to a practice not merely obsolescent but actually obsolete. Thus, also, the rapid development of the alternating-current lighting system with high-potential primaries feeding through transformers, the low-potential distribution circuits, in an almost equally brief time made the Edison three-wire underground system practically of the past.

4.—Inadequacy—the loss of value because the product of the plant, though meeting the requirements as to character, is of insufficient quantity—is, like obsolescence, uncertain as to its occurrence and variable as to progress, though not to the same extent as the former; and, like it, its curve, in terms of time and loss, may be of almost any form.

These four elements are so different in character that it is hardly possible to treat them properly together. If the system under consideration is of such extent that the average of conditions is a fair general average, life tables may be applied with very good results, so far as organic and functional depreciations are concerned. Local conditions, however, often make the system average quite different from that of the tables, with corresponding error unless proper correction factors are used. Obsolescence and inadequacy, at best, can only be guessed at.

The author truly says of "the reproduction method, or cost new less depreciation," "This line of evidence is only one source of information as to value." The fair value of the property used and useful for the public is neither the cost to produce nor yet the cost to reproduce; it is the capitalized earning power. It has been argued that for rate-making the earning power cannot be considered, as it is a direct function of the rates to be regulated, and it is hard to escape the conclusion that—at least where there is competition—rate-making must of necessity be an arbitrary procedure. Economic laws, more powerful even than governmental commissions, will compel the practical equalization of rates, even though different values of competing utilities would otherwise permit them to charge different rates for the same service.

Mr. Harte.

In determining physical value, the Courts almost universally—if not entirely so—have held that depreciation must be considered. It is difficult to find logical grounds for doing otherwise. Use—and for that matter disuse as well—causes losses of quality, quantity, and, if extended, of efficiency. That these losses ought to be made good by the owner, or that there exists a fund dedicated to such making good, in no way changes the facts that the loss has occurred, although such outside conditions may offset the physical loss and result in an unchanged or even enhanced value when the two are considered together.

With the proposition to determine past depreciation "on the basis of a sinking fund" there will be much disagreement. Past depreciation is a fact which, except as to its rate of progress, is usually ascertainable without great difficulty, and it should be actually ascertained if the determination is to stand investigation.

A depreciation fund properly secured may be included as one of the physical parts of a property, and, if equal to the amount of depreciation, will, of course, offset it, but in such case the depreciation itself must be determined in order to see if the fund is adequate; it is equally possible, unless adjusted frequently, that it may be greater or less. Nor is the writing off of such an item on the books without dedication of the actual money merely an opinion. Properly written off, it stands as a liability of the property, reducing by its amounts the net earnings of the prosperous plant, or adding to the deficit of the losing venture.

Under the caption "Utilities Commonly Require Growing Plants" the author states that extensions produce a developing series of increments, each with its own depreciation. Although this is literally true, the situation is far less complex than the statement would indicate, because much of an extension merges into and thereafter is treated as a part of the older installation, and depreciation is taken as an average on the whole. Building extensions of comparatively small amount, additions to piping and wiring systems, all such are adaptable to this treatment, leaving only the larger individual items to be dealt with separately.

It might well have been said that the earning power of a partly worn plant is almost invariably greater than that of a new one. Smooth operation, and the maximum efficiency, are had only after the very appreciable physical losses due to what Mr. Wilgus, in his recent paper "Physical Valuation of Railroads,"* aptly called the "educational period."

The author states that "One of the reasons the Courts have for favoring the reproduction method, or cost new less depreciation, lies in the fact that such procedure includes appreciation as well as excludes depreciation." It is probable that the attitude of the Courts

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 203.

Mr. Harte.

in this matter is due more to the logic of the procedure than to a desire to include appreciation.

The cost of educating the public to the value of the utility, though not attaching to the property in that particular form, remains as a very considerable asset in the going value, which is due to "a fundamental conviction that a utility is really necessary and useful."

In "The Practical Treatment of Depreciation Accounts" the author apparently considers safe only that fund established with some trust company. Aside from the fact that trust companies have failed, and doubtless will do so in the future, such companies find the necessary monies to meet fund interest, overhead charges, and profit, in other securities, and, if the utility by direct investment can save the middleman's profit and overhead charges, and thus reduce the investment necessary to produce the required result, it would seem but fair thus to permit; the matter is purely the question of fact as to whether or not the "securities" are such in more than name, and whether they are a part of the property, or have passed out of it. The first calls for expert financial knowledge; the second must be evident from the books.

A reasonably safeguarded fund or investment for renewal purposes, in a total valuation, should be considered as much a part of the property as the material which it will presently replace. Such replacements for the most part can be made economically only after considerable wear and consequent loss in physical value. If this physical loss is not excessive, and is properly set up on the books as a liability, it is obviously unjust to deprive the owner of its proportion of earnings merely because of its changed form.

The author's first conclusion, that a trust fund to meet depreciation if "properly computed and accurately kept"—this whether in this connection "kept" has reference to the bookkeeping or the actual holding—should be considered a part of the property "used and useful for the public," would seem obvious.

The second conclusion, that the fund must be "actually in hand," is also obvious, if a reasonable interpretation is put upon "in hand." To say, however, that proper book entries do not constitute such condition is, to put it mildly, unfair; carried to its logical conclusion, such reasoning would preclude the consideration, as assets, of any unpaid accounts.

The third conclusion, that "past depreciation may be computed accurately on the sinking-fund basis," is only warranted when "all the facts of the past are known," in which instance there would seem to be little occasion to compute what is already had. It should not be forgotten that, in the Minnesota Rate Case, there were thrown out of Court, because obtained by hypothetical assumptions, figures for land values which were undoubtedly very close to the facts. For the future,

knowledge of the past will often establish correction factors to apply to and make applicable life tables, so that organic and functional depreciation can be predicted with reasonable closeness, but the possible effects of obsolescence and inadequacy can only be guessed at, in the light, respectively, of the development of the art and the local conditions. Mr. Harte.

Conclusion four, that depreciation accounts should be kept by groups having similar life characteristics, and should be revised from time to time, is good, and might well call for considerable detail in the groups. It should be always remembered, however, that such accounts are only estimates, the relations of which to the facts can only be known by actual comparison.

Conclusion five, as stated, that the use of a reserve or sinking fund for private gain precludes its consideration as a factor of value to the utility, is sound only as it applies to such portion of the return from the fund as becomes "private gain." The use of funds set aside for the specific purpose of a reserve or sinking fund in the purchase of securities or in other forms of loan does not destroy the asset unless the security therefor, whether bonds, stocks, or personal notes, loses value; nor if such security pays a rate of interest higher than necessary for the calculated fund, and this excess be withdrawn and otherwise used, does it impair the protection of the remaining portion.

W. KIERSTED, M. AM. SOC. C. E. (by letter).—Mr. Alvord's interesting paper on depreciation appears to be largely a discussion of the paper by Mr. Grunsky,* or at least to have been suggested by the views set forth in that paper. Mr. Kiersted.

In this discussion Mr. Alvord raises four distinct questions, namely:

Shall allowance be made for depreciation of physical structures in computing value of a public utility property by the reproduction method for rate-making?

Should a sinking fund, created to take care of depreciation, be allowed to earn a return—in fact, to earn the same rate of return as other portions of the property?

Should a sinking fund thus created be considered as a part of the property?

Should the units of property be grouped according to their respective life limit in accounting?

A difficulty at once arises in discussing these questions from the fact that the viewpoint of the author is not made perfectly clear. One can readily conceive of lines of procedure under the reproduction method of computing value which might admit of opposite answers to all the questions mentioned. Under the circumstances, the dis-

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 770.

Mr. Kiersted.

cussion of these questions is likely to develop divergent opinions, depending on the viewpoint of the writer.

The reproduction method of valuation seems to require more hammering to reduce it to proper form and more clearly to restrict or fix the line of procedure; and, until this is done, there is little hope of arriving at a conclusion on questions of the kind raised by the author, especially when considered somewhat abstractly. In many instances computations relating to the rate of return on values found by the reproduction method have not sufficiently discriminated between a fair rate of return on the value of the depreciable and the non-depreciable property, on the value of the tangible and the intangible property, and on the value which is actually earned and that which includes an unearned increment. Such questions as these seem to have been overlooked in most of the rate cases of recent years. Moreover, most of the units going to make up the value of a public utility property possess no value except for the particular purpose for which the public utility is used, though other units possess an intrinsic value of their own, entirely apart from and independent of the public utility with which they are connected. Investment in units of one class is obviously more hazardous than in the other class, and there should be a corresponding difference in the rate of return to which the respective classes of property may be entitled. The questions raised by the author fall in a similar category, and unless they can be discussed thoroughly and comprehensively in connection with all other questions which enter into the computations of value by the reproduction method, or by any other method, no conclusive answer can be given to them.

The writer's discussion will be brief, and directed largely to simplifying, rather than complicating, the questions propounded for discussion.

Several valuations of water-works properties by commissions of experienced men, for the purpose, among other things, of rate-making, have been carefully analyzed and platted for the purpose of seeing how the methods of valuation therein used would work out in practice. However, only that part of one of the analyses which seems to apply to this paper, will be considered. The value of this particular property was computed by the commission in accordance with the reproduction method, as used in many of the late valuation cases, and allowance was made for depreciation as well as for enhancement of value and for unearned increments of value. Depreciation was computed on the sinking-fund basis by assuming a life for thirty or more units going to make up the physical property, with sinking-fund increments uniformly bearing interest at the rate of 3½% per annum, regardless of whether the unit under consideration was short-lived or long-lived.

Mr. Kiersted.

Under the assumptions made in the writer's analysis, the composite property might or might not be assumed to have a definite life, but, for the purpose of a part at least of this discussion it is considered as possessing definite life—a life limit having been assumed for all the units of the depreciable property.

On the diagram, Fig. 1, are platted two curves, each point in each curve being platted with reference to the average age and equivalent annual percentage rate of depreciation of the composite property. One, the full-line (upper) curve, is for convenience termed a definite-life curve, the other, the broken-line (lower) curve, is termed a perpetual-life curve. Average age is computed in the usual manner by the weighted method. The equivalent annual percentage rate of depreciation is found by dividing the total depreciation, as of the date under consideration, by the average age of the composite property, as of the same date. Whenever a break occurs in either of these curves it indicates that some one of the many units considered has reached the limit of its assumed life. It is assumed that throughout the whole period under consideration the total investment in the physical property remains the same. This assumption is met in the analysis by making two computations whenever any unit, going to make up the composite property, reaches its life limit. One computation consists of determining the average age and the total percentage depreciation of the composite property at the time when a unit reaches its life limit and is depreciated 100%; the other computation consists of determining the average age and total percentage depreciation as of the same year and date as the preceding computation, taking into consideration the new or substitute unit as of the same class and cost as the replaced unit. The new curve, starting with the substitute unit, continues unbroken until a second unit reaches its life limit, when another break occurs and two similar computations are made and a new curve started, and so on until all the units have been thus considered, making what is for convenience termed a cycle.

During a cycle of this particular property the number of units replaced by new ones of the same kind and cost are as follows: four units four times, eight units three times, nine units twice, and ten units once.

These curves serve no particular purpose except to illustrate the variation of the equivalent annual percentage rate of depreciation of the composite property during different periods of a cycle. They indicate a progressive and regular increase of the equivalent average annual percentage rate of depreciation until units begin to disappear, which is characteristic of the sinking-fund method of computing depreciation. The computations made in connection with the analysis lead to the following suggestions:

Mr. Kiersted.

First, the definite-life (full-line) curve:

a.—The total percentage cost of replacements during a cycle is 132.5% of the total investment in the physical structures composing the composite property, equivalent to the amount of an annuity of 0.67% of the investment in physical structures, earning interest in a replacement fund at the rate of 3½% per year during an average age period of 63 years.

b.—The value of the investment at the close of the cycle is the same as at the beginning of the cycle, the replacements having been made promptly as each unit reached the limit of its assumed life period.

c.—In order that the annuity of 0.67% of the investment in physical structures may amount to the cost of replacement during a cycle, the annuity and interest increments accruing thereon must remain undisturbed in a replacement fund during the entire cycle.

d.—If the owner of the property allows the replacement fund to remain intact, and uses new money to make replacements, then at the expiration of a cycle his property is worth 100% plus the monies in the replacement fund.

e.—If the replacement fund accumulates in the manner before stated and remains intact, and the owner makes no replacements with new money (assuming such a condition to be possible) then at the expiration of a cycle he has no property, but is the owner of a large portion at least of the monies in the replacement fund.

f.—If the owner of the property makes replacements with money taken from the replacement fund, as units need to be renewed, then such monies as may be taken from the replacement fund cease to draw interest as a part of that fund, but earn, as a part of the plant, their *pro rata* of the fair return due the owner and of the annuity going into the fund. The result is a deficit in the replacement fund when computed as per "*a*" and "*c*", of a large amount at the end of a cycle. In order to prevent such a deficit, and at the same time to permit monies to be taken from the replacement fund for renewals of plant as conditions demand, the annuity should be about 0.95% of the investment in physical structures.

g.—Throughout the entire cycle, computations of the fair return and of the annuity to the replacement fund should be based on 100% value of the investment.

h.—Replacements having been made to the property as needed, and the property thereby maintained at 100% value, there is no need of a sinking fund to return the original investment, because the property possesses the characteristics of perpetual life.

i.—Assume the owner to sell the property at some time during a cycle, the replacements having been made from monies accumulated in the replacement fund, then the property would be worth to the

Mr. Kiersted.

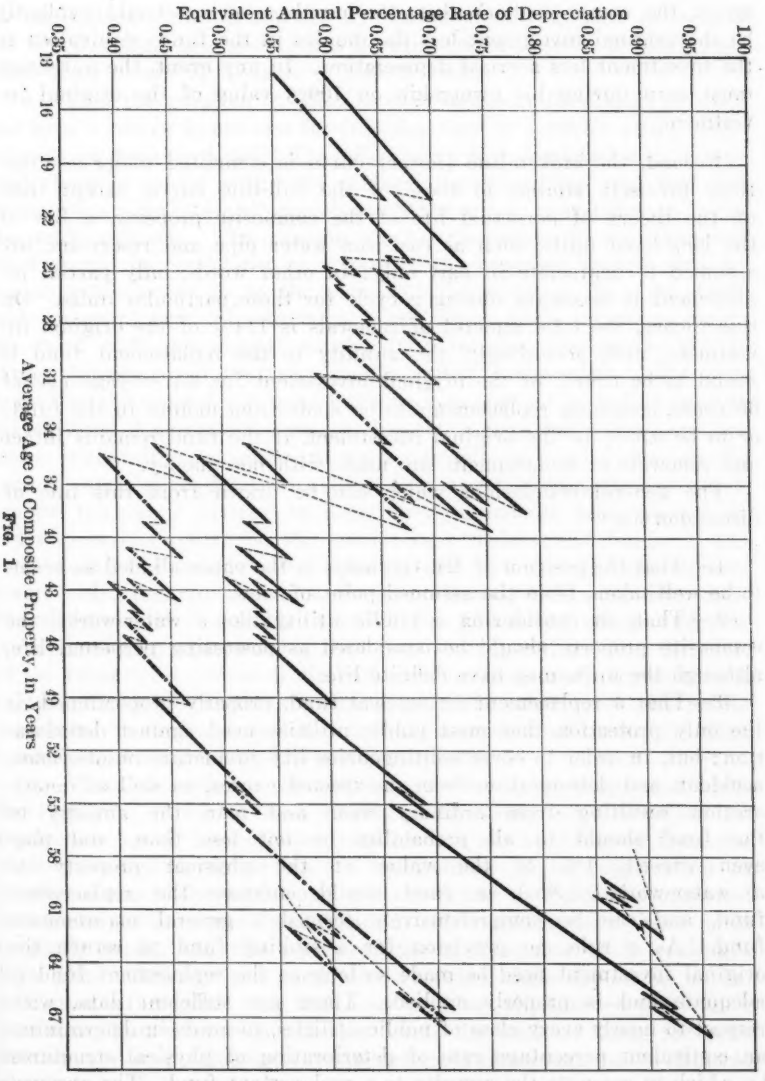

FIG. 1.

Mr. Kiersted.

purchaser the full amount of the investment, provided the remaining monies in the fund go with the property. If the monies in the fund go to the owner (seller) then the purchase price should evidently be the original investment less the monies in the fund—equivalent to the investment less accrued depreciation. In any event, the purchaser must earn during his ownership on 100% value of the original investment.

Second, the broken-line (lower) curve is computed under assumptions precisely similar to those of the full-line curve, except that, on the theory of perpetual life of the composite property, a few of the long-lived units, such as cast-iron water pipe and reservoirs, are assumed to depreciate in part only; in other words, only partial replacement is necessary during a cycle for these particular units. On this theory, the total amount of renewals is 114% of the original investment, and, accordingly, the annuity to the replacement fund is found to be 0.80% of the original investment for an average age of 65 years, assuming replacements to be made from monies in the fund; or to be 0.53% of the original investment, if the fund remains intact and renewals or replacements are made with new money.

The general conclusions which can be drawn from this line of discussion are:

1.—That the position of Mr. Grunsky, in the paper alluded to, seems to be well taken, from the assumed point of view.

2.—That, in considering a public utility like a water-works, the composite property should be considered as possessing perpetual life, although the units may have definite life.

3.—That a replacement or renewal fund, properly proportioned, is the only protection that most public utilities need against deterioration; but, in order to cover contingencies like premature obsolescence, accident, and deterioration from unexpected causes, as well as deterioration resulting from ordinary wear and tear, the annuity to the fund should in all probability be not less than, and may even exceed, 1% of the value of the physical property of a water-works. Such a fund would embrace the replacement fund, and can be comprehensively termed a general maintenance fund. As a rule, no provision for a sinking fund to return the original investment need be made so long as the replacement fund is adequate and is properly applied. There are sufficient data, with respect to nearly every class of public utilities, to guide in determining an equivalent percentage rate of deterioration of physical structures by which to compute the annuity to a replacement fund. The annuity itself will doubtless vary for different properties of any given class. The annuity to a fund should be considered as earning interest at

sinking-fund rates, the interest being considered, of course, as a part of the fund. None of the increments to a replacement fund should be capitalized. The monies in the fund should be used as needed for replacements, and should not be surrounded by a wall which prevents their proper application in that direction. Mr. Kiersted.

4.—That the question of whether a replacement fund shall or shall not earn a return is not one for consideration by a public utility commission in definite detail. The office of such a commission is to see that there is a fair return for rendering good service, and that the properties are maintained in such condition and so operated as to serve the public properly. The question whether the monies in a replacement fund should be considered as a part of the property for use only in replacements or to go to the owner of the property, is a debatable and important one. Should it go to the owner, he is obliged to credit the fund with the regular sinking-fund interest increments, but it cannot be conceived that any public utility commission would seek to destroy the incentive to good business management by ruling against the earning of a return on monies in such a fund, so long as replacements with full-value units are made promptly as needed; nor should such a commission delay in calling to account a management which ignores the public interest by delaying replacements when needed, in order to earn a return on the monies in a replacement fund. If the fund remains attached to the property and is to be used for replacements only, the annuity must be proportioned with some liberality, in order to avoid, if possible, a deficit; but if a deficit occurs and new money goes into replacements, then the owner is entitled to a re-rating of the property, a return of the value of his new-money replacements, or an increase of capital investment. On the other hand, the public is entitled to similar consideration under reverse conditions. In other words, properties must be re-rated periodically.

5.—That depreciation should be considered in connection with the valuation of the physical structures of public utilities on the reproduction basis. Depreciation may or may not be deducted from the value thus found, depending on the manner of the application of monies in the replacement fund and the extent to which the unearned increment enters into consideration. If replacements have been promptly made, and the policy of the management is to maintain high plant efficiency and good public service, there should be no depreciation of original cost value of existing physical property in a rate case; but, where reproduction forms the basis of value for rate-making, and such value includes an unearned increment, due to changed physical conditions or enhanced values of certain units resulting from city environment, and the same rate of return is allowed on these elements of value as on other portions of the property, then depreciа-

Mr. Kiersted.

tion should be allowed in computing fair return; but if the enhanced values and unearned increments of value were put in a class by themselves and were allowed such a rate of return as may be equitable, then depreciation of the physical property might be as consistently ignored in a rate case based on reproduction as when based on original cost value.

6.—That, in accounting, there is no necessity for dividing a property into groups of units according to some assumed life and charging each account with depreciation in accordance with some mathematical rule. The property should be considered as a whole, or in groups arranged by structural classification, deducting from the values thus recorded in the accounts the cost or value of any article or unit that is abandoned or replaced, and adding to the account the substitute article or unit. In doing so, proper discrimination should be drawn between minor renewals belonging properly to the operating account and replacements which actually affect the investment. Every engineer must concede that the place for working out details and for clarifying and simplifying any plan or specification is in the office, in order to render the work of the field parties as simple, clear-cut, and free from the danger of error as possible, and it can be conceived that similar principles should apply to accounting.

Although much more can be said on the questions under discussion, if considered in their relation with the general subject of valuation, and from a practical rather than an academic point of view, the writer is not inclined to extend the range of discussion beyond that laid down in the paper, except to add one or two remarks, particularly as the writer's discussion of Mr. Grunsky's paper presents relevant views which Mr. Alvord seems to indorse, in part, at least.

The writer has stated previously that the reproduction method of valuation needs more hammering to reduce it to proper form for general use. The attempt to apply rules to valuation work, with mathematical precision, is certainly a mistake, and leads the adherents of these rules into error in matters which necessarily involve the use of an enlightened and experienced judgment unfettered by precedent or rule. So many times the "yard stick" of value (to use the term of another) in contact with a mind overheated with the discovery of some element of value hitherto disregarded, or with some new idea, has been so expanded as to distort a line of reasoning believed at the time to proceed from an elevated or progressive point of view; or, on the other hand, the "yard stick," with the middle half cut out and the ends of the remaining portion joined with unaltered dimension at either end, has been used as though of up-to-standard length. There is no possible way of reconciling the differences thus encountered, or of bridging the wide gap exposed in the deductions thus made, except

by going back and standardizing the "yard stick." In other words, fundamental principles must be agreed on, and these principles must be applied consistently, intelligently, and cautiously, and with due consideration of the character, condition, and individuality of each property to be valued. In no two instances will the application of the principles be the same, but the results of the work of two or more appraisers should not vary so much as to be irreconcilable, or as to cause confusion of mind for those who hope to be profited by the expert's wisdom. Mr. Kiersted.

GEORGE B. STONE, ASSOC. M. AM. SOC. C. E. (by letter).—The question of depreciation of public utility corporations is of great moment at the present time to all members of the Profession, and especially to engineers engaged in the work of valuation of public service corporations, and is a subject of vital importance to both the public and the financial interests. Mr. Alvord's paper is of great interest, and he has presented his view of the question clearly and concisely. To the broad discussion that must take place before we finally come to an agreement, his paper is a valuable contribution. Mr. Stone.

The writer's experience has been entirely in railroad work, and in the remarks that follow he has confined himself to that point of view.

The valuation of common carriers, as outlined by the Federal law, gives a suggestion of "the cost of reproduction less depreciation" and the question immediately arises: "What shall this depreciation be, and how shall it be disposed of? The writer cannot agree with Mr. Alvord that depreciation is the same for all purposes of valuation, and will attempt to outline the reasons.

Depreciation for Rate-Making and Fair Return.—W. J. Wilgus, M. Am. Soc. C. E., in his paper, "Physical Valuation of Railroads,"* stated the question of depreciation for the purpose of rate-making very clearly and convincingly from the standpoint of the accountant working with an engineer on this subject, and the writer agrees absolutely with those views. The writer believes, however, that there are still other and equally important reasons why depreciation, as the word is commonly taken, should not be deducted from the cost of reproduction new, as of the date of the valuation. Stripped of all theories and technicalities, valuation for the purpose of rate-making becomes a question of allowable rates for a given service due to the corporation from its patrons. The Federal law suggests that these rates shall be determined on a basis of fair return based on the cost of reproduction new less depreciation, but it does not state how this subject of depreciation shall be considered, and has left unsettled a question which is open to much discussion and controversy. The object of the law was to furnish a means of settling many of the disputes that have arisen

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 208.

Mr. Stone.

over the question of rates in the past, and to prevent and settle all such controversies in the future. Such being the case, the consideration of depreciation for rate purposes becomes one of service, and not physical value, unless the service of a given property has fallen below that which might reasonably be expected from a given investment. If it is found, in the valuation of a given property, that the service is less than might reasonably be expected from a given investment, then the property should be assessed a depreciation charge equal to the amount of depreciation from this source. This applies to a well-managed, going property, for if a property has been poorly managed, and there is evidence of needless expense and unwarranted waste, no valuation based on the cost of reproduction of its physical parts would ever give a correct value for rate-making or for any other purpose except that of taxation. Many properties will come between the extremes, but the principle remains the same.

Depreciation for Taxation.—The law, as practised, in regard to the taxation of all property, recognizes but one value: the amount that a given property will bring at forced sale; and, for taxation purposes, depreciation assumes an entirely different meaning from that for rate-making; in that it becomes a recognizable physical value, it becomes a problem of actual worth as shown from the inventoried cost new less any depreciation value due from any cause that affects its physical condition. It is a problem of actual physical worth, and cannot include anything but its true dollars-and-cents value. "A" owns a certain lot of land for which he paid $500 and can sell it for this amount at any time that he chooses, but, by waiting a little, he can sell it for $1 000. The $500 is the quick-sale or taxable value, and the larger figure is the sale value. This principle of taxation has been generally recognized by the Courts in taxation cases. The general principle of this subject is very simple, and the writer fails to find any reason for complicating it by the adoption of assumptions that do not exist in every-day practical railroad management; nor does he believe that any valuation based on theoretical assumptions will stand in the Courts. Depreciation for taxation can be the loss due to physical age of a property and nothing else, under the present construction of the tax laws.

Depreciation as Applied to Sales Value.—This phase of the subject is very closely allied to that of taxation, but has many features that prohibit the combination of the two under one head; it is also closely allied to depreciation for the purpose of rate-making, in that it has a value which is dependent on service. There are so many phases to this portion of the subject that the writer does not believe that, at this time, it would be either good business or good engineering to attempt to lay down a general law on the subject; nor, at the present stage of the matter, could a satisfactory general law be laid down. Every

Mr. Stone.

carrier has a different problem to solve when it comes to the placing of a sale value on its property. The appraiser has the simplest portion of his work complete when he has finished the physical inventory of the property and made the proper deductions due to the physical depreciation of the property as of any certain date. He has many questions to ask himself: Is the location as it stands the best to be found, considering the traffic? In case the line were sold, would the purchaser rebuild any portion of it for economic reasons? Are there any competing lines built on a more economic basis which affect the earning power of the road under consideration? All these, and many others of a like nature, must be answered equitably before depreciation for sale value can be determined. Such questions as these have values of depreciation, and the appraiser must determine the true values and consider them a part of his appraisal. One road may not have cost double what its rival did, and yet the service of both roads is the same. There is a definite depreciation value here, chargeable against the more costly road, in case an appraiser was placing a sale value on it; but, another critic will say, there would be an appreciation value in favor of the cheaper road in case a sales value was to be placed on it. This is very true; there is a question of which value to apply, but that is for the appraiser to settle. The main point that the writer wishes to make is that there are values of depreciation for sales purposes which do not apply to either the taxation or the rate question.

AMERICAN SOCIETY OF CIVIL ENGINEERS

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

REINFORCED CONCRETE RESERVOIR AND COAGULATION PLANT AT ST. LOUIS, MO.

Discussion.*

BY MESSRS. J. K. FINCH, ALEXANDER POTTER, AND CHARLES B. BUERGER.

Mr. Finch.

J. K. FINCH, JUN. AM. SOC. C. E. (by letter).—In some cases reinforced concrete has been substituted for steel in the construction of tanks and stand-pipes, because it was believed it would result in economy, both in first cost and maintenance, and because such structures are generally on high ground, where they can be seen from afar, and it was hoped that a more satisfactory architectural effect could be secured by its use. The first of these expectations has generally been realized, but not the latter, not on account of the material, which is admirably suitable for architectural treatment, but because the failure to obtain a truly water-tight construction causes the marring of the surface of the structure by the formation of moist spots, due to "sweating," and patches of efflorescence. It has been pretty well established that the chief difficulties are:

1. Poor concrete;
2. Vertical cracks in concrete due to excessive stretching of steel under hoop tension;
3. Horizontal cracks between days' work, due to difficulty of joining old and new concrete, and the fact that concrete shrinks in setting and the successive layers are held apart by the vertical steel necessary for supporting the hooping rods; and
4. The formation of a horizontal crack, about 5 ft. above the base, in all cases where the bars in the floor or base have been turned up into the side-walls.

*This discussion (of the paper by Edward Flad, M. Am. Soc. C. E., published in December, 1913, *Proceedings*, and presented at the meeting of February 4th, 1913), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Finch.

The remedy for the first is good materials and workmanship. A solution of the second difficulty has been proposed by H. B. Andrews, M. Am. Soc. C. E., in a paper entitled "A New Theory for the Design of Reinforced Concrete Reservoirs,"* presented before the Boston Society of Civil Engineers in 1910. This is the method followed by Mr. Flad in the design of the St. Louis tank. The writer desires to call attention to the fact that Mr. Flad, however, has used a working tensile strength for the 1:1½:3 limestone concrete of 290 lb. per sq. in., which appears to be excessive. It must be borne in mind, of course, that economy demands the use of a low factor of safety, say 1½, for the concrete, which is ample, as the ultimate safety of the structure depends on the steel, but this figure, 290 lb., has been taken apparently from Mr. Andrews' paper, in which he proposed this stress for a 1:1:2 concrete, not a 1:1½:3 mixture.

It is unfortunate that there are so few tests of concrete in tension on which to base a satisfactory working stress. The tests that have been made show a considerable range in values, due to the effect of different aggregates, methods of mixing, etc., and, generally, only unreinforced specimens have been tested. M. Considère made a number of experiments on reinforced concrete in tension, and concluded that the action of the reinforcing steel was to distribute the stress throughout the concrete and enable the latter to take a tensile loading considerably higher than the plain unreinforced material. It was shown later, however, that this was not proved by the tests, as M. Considère's method of computing the stress in the concrete and steel was incorrect. In fact, it was shown that a reinforced specimen developed cracks, and the concrete practically failed at about the same load as an unreinforced specimen. A few tests have been made at Columbia University on 6 by 6-in., 1:3:5 briquettes reinforced with 0.68 to 4.26% of steel, which showed a failure stress in the concrete, based on the break in the stress-strain curve of 205 lb. per sq. in., which is about the same as would be expected from an unreinforced specimen.

Mr. Andrews obtained his figure, 290 lb. for 1:1:2 concrete from a few tests he had made, which gave an average of 281 lb. per sq. in., by increasing his test value by 25 and 10%, which gave him 386 lb., which he considered as the ultimate strength for a large reinforced specimen, and that 290 lb. was sufficiently lower than this to be used in the design. The increase of 25% was to allow for "the usual increase in strength of large size over small specimens," his test pieces being 4 by 4 in. in cross-section; the further increase of 10% was to allow for the effect of reinforcing steel, and was probably based on M. Considère's deductions. Neither of these increases seems to be justified by any tests yet made, but Mr. Andrews' tests did give rather

*Journal, Assoc. Eng. Soc., Vol. XLVI, 1911, p. 391.

low values. The following stresses are estimated to be fair values for the quality of concrete used in tank work: Mr. Finch.

Mix.	Age, in days.	Ultimate strength, in pounds per square inch.
1:1 :2	30	300-400
	90	400-500
1:1½:3	30	250-350
	90	350-450
1:2 :4	30	200-300
	90	300-400

The working stress should depend on the length of time to elapse before the tank will be filled, but 290 lb. per sq. in. appears to be high for a 1:1½:3 mixture.

There seems to be no remedy for the difficulty due to field joints, except pouring in one operation, which should be done whenever possible. Proper care in cleaning the surface of the old concrete, and the use of copper strips or dams, will doubtless do much to remedy this trouble.

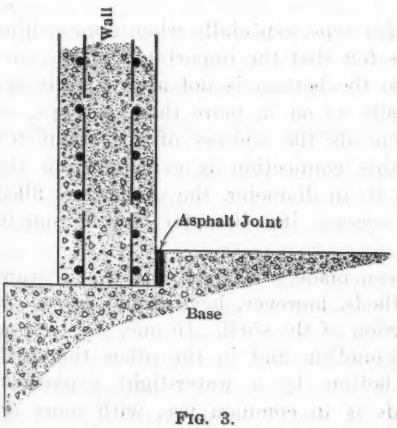

FIG. 3.

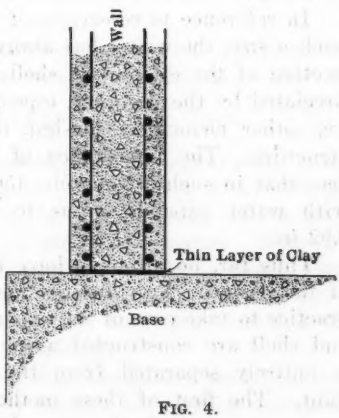

FIG. 4.

The formation of a horizontal crack, in cases where the bottom reinforcement has been run up into the sides, is due to the fact that the lower part of the side-walls of the tank is prevented from stretching under the hoop tension, due to the restraint of the bottom reinforcement. Indeed, the writer is of the opinion that in the lower part of Mr. Flad's design the wall acts as a cantilever in carrying the water pressure, and little or no hoop tension exists. He cannot see why this method of carrying up the bottom reinforcement has been followed in most cases. There is apparently no reason for not designing a tank simply as a vertical section of pipe resting on, but independent of, the base, as shown in Figs. 3 and 4. The pressure on the joint between

Mr. Finch. the sides and base should be investigated, of course, for the effect of wind and also for possible upward water pressure, but, in the majority of cases, this joint will always show an ample positive pressure.

The writer has used the form shown in Fig. 3 in preparing a design for his students in reinforced concrete, and has since learned that Mr. P. D. Johnson, Hydraulic Engineer of the Ontario Power Company, Niagara Falls, has made tests of the type of joint shown in Fig. 4, and has actually constructed the No. 2 Surge Tank of the Ontario Power Company on this principle. This tank is 70½ ft. high and 79 ft. in diameter, and no cracks have developed. The writer understands that a thin coating of clay was placed on the base under the walls before the wall concrete was deposited.

Mr. Potter. ALEXANDER POTTER, ASSOC. M. AM. SOC. C. E. (by letter).—As far as the writer knows this is the largest reinforced concrete reservoir in America of a type in which the hydrostatic pressure is resisted by ring tension; therefore it is of more than usual interest to the Profession.

In reference to reservoirs of this type, especially when approaching such a size, the writer has always felt that the importance of the connection of the cylindrical shell to the bottom is not always fully appreciated by the designer, especially as on it, more than, perhaps, on any other element of design, depends the success of the completed structure. The importance of this connection is evident from the fact that in such a reservoir, 150 ft. in diameter, the shell when filled with water expands so as to increase its diameter approximately 0.92 in.

Thus far, no attempts have been made to standardize this feature of the design. Two distinct methods, however, have been evolved in practice to take care of the expansion of the shell. In one, the bottom and shell are constructed as a monolith, and in the other the shell is entirely separated from the bottom by a water-tight expansion joint. The first of these methods is in common use, with more or less success, and is the one which seems to have been used successfully in constructing this settling tank.

Such a rigid connection, to be successful, calls for heavy steel reinforcement throughout the entire bottom, which, for economy, must be of as thin a section as possible so that, by stretching, it can readily adapt itself to the increase in diameter when the reservoir is full. This reinforced concrete bottom must be designed so that it can stretch in all directions on an average of 1 in 2 000 without developing cracks of sufficient extent to impair its water-tightness. There is every reason to believe that the elongation in the bottom is not distributed uniformly and that the bottom is stressed most in its outer portion and very little, if any, in its central portion. This unequal

Mr. Potter.

distribution would tend to give radial elongations in the outer circumference of the bottom considerably greater than the average value. It appears, however, that as long as the bottom is quite thin and is reinforced in all directions with at least 0.5% of steel possessing a high elastic limit, such a bottom can be maintained practically water-tight. Ordinarily, such a heavily reinforced thin bottom must be supported on a rigid and smooth foundation in such a way as to permit of as free expansion as possible. The bottom of the cylindrical shell must also be heavily reinforced to resist the stresses due to the bending moments set up in it by the restraining action of the bottom.

A rigid connection, such as used in the St. Louis reservoir, to be successful, is wasteful of structural material. It would appear to be more economical to use some type of water-tight expansion joint between the shell and the bottom, so as to permit the shell to expand irrespective of the bottom. This latter form of construction has already been used to some extent in circular tanks of relatively small diameter. A discussion on this point is invited, as the use of such expansion joints in tanks of large size, if proven successful, will tend to a more economic form of construction.

Another point on which there appears to be a wide difference of opinion is the proper thickness of the concrete section to be used in designing the shell. The author derives the formula, $T = \frac{pr - 9A}{12c}$ for the proper thickness of the concrete wall at any point, based on the assumption that vertical cracks are not likely to develop under a tension of 290 lb. per sq. in. in the concrete, and a ratio of 10 for the modulus of elasticity of steel to concrete. With the unit stresses assumed, the formula reduces to the simpler form that at any point the thickness of the concrete must be 42.7 times the area of the steel per inch of height of wall, thus limiting the steel reinforcement in the shell to 2.35 per cent.

The assumption on which the foregoing results are based appears to be an arbitrary one. There are any number of existing structures in which the ratio of steel to concrete exceeds 2.35%, and in which the concrete remains practically water-tight. Perhaps the most striking example can be found in cement-lined, wrought-iron pipe. In such pipe the steel reinforcement is frequently as high as 10%, and yet, under the high unit stresses to which the wrought-iron shell is often subjected in service, the cement lining possesses sufficient ductility to remain intact after years of service. Many sections of such pipe have been removed by the writer from distribution mains, the lining being found as perfect as on the day when laid. There are other structures, such as reinforced concrete pipe and stand-pipes, in which the ratio of steel to concrete in the shell exceeds 2.35%, which appear to maintain their water-tightness.

Mr. Potter.

In a circular reservoir, the concrete in the shell performs two distinct functions: first, to render the structure water-tight; and second, to resist, in combination with the steel, all stresses due to bending moments which are likely to develop in the more or less rigid structure. The thickness of the concrete lining required for water-tightness, theoretically, is entirely dependent on the density of the concrete and the hydraulic head to which it will be subjected. Theoretically, therefore, it would be possible to use a very thin concrete section, provided the concrete was dense and water-proof, and the steel reinforcement very closely spaced. It is not found practicable, however, to do this. To build a truly circular reservoir is impossible. Owing to the lack of sufficient flexibility on the part of reinforced concrete, heavy bending moments are set up in the shell, due to irregularities of shape, and these must be resisted by the concrete in combination with the steel. It can readily be shown that, with only one row of circumferential reinforcing bars, the bending moments with their resultant stresses are very great and require a heavier concrete section than when two rows of circumferential reinforcing bars are used. The writer agrees with Mr. Flad that it is advisable to limit the percentage of steel reinforcement in the shell. The rule given by him, therefore, based on an apparently arbitrary assumption, appears to be conservative, especially when two rows of steel reinforcement are used. With only one row, it may be advisable to limit the ratio of steel to concrete to 1%, especially in reservoirs of large diameter.

As most engineers are, perhaps, more interested in the general subject of water purification than in the details of reinforced concrete design, the writer takes the liberty, without fear of unduly prolonging the discussion, to remark on the tank from the operating standpoint.

To remove the settled solid matter from this settling tank, it is necessary to draw off the water and place the tank temporarily out of commission. This is likely to happen at a time when the character of the water is such that it will need treatment most, and when the entire settling capacity of the water purification plant is most needed for efficiency. Unless such tanks are cleaned out regularly, the sludge deposits will greatly reduce their settling capacity, thereby lowering the efficiency of the settling process.

The writer has always been of the opinion that a tank in which the settled suspended and precipitated matter can be removed at intervals, without interfering with the operation or efficiency of the tank, possesses considerable advantages over one which must be emptied and put out of service to remove the deposited sludge. Such a basin operating continuously has a number of advantages over one which is operated intermittently. There is considerable saving in the

size of the settling basin when the settling process is carried on continuously. This saving may amount to as much as 50% over the intermittent installation in which two basins are used, decreasing somewhat with the number of basins. When the settling basin is operated continuously, its capacity is practically always available. This is not the case with the intermittent type. Mr. Potter.

There are a number of water purification plants in which the settling tanks are operated continuously. Without interfering with the operation and efficiency of the tank, the sludge is removed daily, and while it is still in a semi-liquid condition, before it has had time to compact. Settling tanks of this type have been used by the writer at McKeesport, Pa., and Georgetown, Ky. (both water-softening tanks), and also in the settling tank at Muskogee, Okla. In all these tanks, the sludge removal is accomplished by having the bottom of the settling compartments perforated with $\frac{1}{2}$-in. to $\frac{3}{4}$-in. circular holes not more than 3 ft. from center to center in all directions. These holes discharge into an under-drain system leading to a common sump. Quick-opening valves are used to regulate the sludge discharge, and when such a system is well designed the possibility of the under-drains becoming clogged is very remote. All these plants are now in successful operation. The oldest is at McKeesport, and has been in continuous operation since 1907.

The cost of properly under-draining a settling tank so that is can be operated continuously is not excessive. For instance, the Muskogee settling basin,* constructed of reinforced concrete, 212 ft. square, 18 ft. deep, and holding 6 000 000 gal., was built for a contract price of $45 000, including all piping, valves, and under-drains.

CHARLES B. BUERGER, ASSOC. M. AM. SOC. C. E. (by letter).—The choice of a circular tension-ring type of tank, in this particular design, leads to the thought that there must be some economical dividing line such that tanks of smaller diameter are more economically built with a tension-ring wall, and those of larger diameter are most economical when built with cantilever walls. Mr. Buerger.

In actual practice the most economical style will depend largely on the particular details of design adopted, the unit stresses, the assumptions as to actions of the various parts, arrangement of metal, thickness of walls, the nature of foundation, and other varying data. There is, however, a general relation which can be established which shows what is for ordinary conditions the approximate maximum diameter for which the tension-ring type of tank is adapted.

Assume an ideal theoretical tank with tapered concrete walls of zero thickness at the top water level and a maximum thickness at the bottom, and assume that the active metal is in all cases 3% of the

* The details of construction and methods of operation are described in the *Proceedings* of the American Water Works Association, 1912.

Mr. Buerger.

cross-section of the concrete, measured from the face of the concrete to the steel. Assume that the active steel is in all cases exactly equal to the theoretical quantity needed, with no allowance for laps or bonds; assume, also, that the steel at right angles to the active metal used to counteract shrinkage or temperature stresses, or to transmit stresses, is the same for the two types. For these conditions the only unequal element will then be the area or volume of the active steel.

Taking all dimensions in feet:

For the tension-ring type wall:

$$T = p\,r = 62.4\,hr, \text{ at any point} = f\,a \quad \ldots\ldots (1)$$

where a = the area of the metal,

and f = the unit stress in the metal.

Calling H the total height of the tank,

$$A\,f = \frac{62.4\,H^2\,r}{2} \quad \ldots\ldots (2)$$

and the volume of steel per foot of tank periphery is

$$V = \frac{31.2\,H^2\,r}{f} \quad \ldots\ldots (3)$$

For the cantilever-wall type:

As before, the total pressure acting on the wall above any plane

$$= 31.2\,h^2 \quad \ldots\ldots (4)$$

The moment of the pressure at that plane,

$$m = 31.2\,h^2 \times \frac{h}{3} = 10.7\,h^3 \quad \ldots\ldots (5)$$

For the assumption of 3% of metal and a ratio of modulus of elasticity of the steel to that of the concrete of 15, calling d the thickness of the wall to the steel

$$0.80\,f\,a\,d = m = 10.7\,h^3 \quad \ldots\ldots (6)$$

$$0.03\,d = a. \quad \ldots\ldots (7)$$

$$a = \sqrt{\frac{0.40}{f}} \times h^{\frac{3}{2}} \quad \ldots\ldots (8)$$

$$d\,V = a\,dh = \frac{0.40}{f} \times h^{\frac{3}{2}}\,dh \quad \ldots\ldots (9)$$

$$V = \frac{2}{5}\sqrt{\frac{0.40}{f}} \times H^{\frac{5}{2}} \quad \ldots\ldots (10)$$

For the dividing line, at which the required steel is the same for both types of wall:

$$\frac{2}{5}\sqrt{\frac{0.40}{f}} \times H^{\frac{5}{2}} = \frac{31.2\,H^2\,r}{f} \quad \ldots\ldots (11)$$

$$r^2 = 0.000066\,f\,H \quad \ldots\ldots (12)$$

Taking $f = 144 \times 15\,000 = 2\,160\,000$

$$r^2 = 144\,H \quad \ldots\ldots (13)$$

$$r = 12\sqrt{H} \quad \ldots\ldots (14)$$

Mr. Buerger.

The general relation appears then that the maximum economical diameter of the tension-ring type of tank is 24 times the square root of the water depth. This relation will be modified in actual designs by several elements not considered in the foregoing. For instance, the quantity of steel to bond the cantilever wall into the floor of the tank has not been considered; and, as this is somewhat more in the cantilever type than in the tension-ring type, correction of this omission would be in favor of the tension-ring type. On the other hand, in the cantilever-wall type it is possible and economical to make the thickness of the wall greater than assumed in the foregoing equations, so that the percentage of metal is less than 3. The addition of this condition will favor the cantilever-wall type.

Applying this relation to Mr. Flad's executed reservoir, with the bottom of the wall at Elevation 97 and high-water line at Elevation 128, and a depth of 31 ft., it appears that the maximum economical diameter would be 134 ft. Mr. Flad's tank is somewhat larger than this, with a diameter of 150 ft.; but there are some conditions stated in his paper which amply explain and justify his choice of design. The foundation is stated to be river silt, and is no doubt ill adapted to support cantilever retaining walls satisfactorily. It is obvious that the more uniform loading given by the tension-ring type of tank justifies the use of additional steel reinforcement.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

TOPOGRAPHICAL SURVEYS MADE BY THE AMERICAN SECTION OF THE INTERNATIONAL BOUNDARY COMMISSION UNITED STATES AND MEXICO.

Discussion.*

By Leonard S. Smith, M. Am. Soc. C. E.

Mr. Smith.

Leonard S. Smith, M. Am. Soc. C. E. (by letter).—This paper is a notable contribution to the literature of topographic surveying, and is of special interest to the writer because of its comparisons with the topographical work of the Barlow, United States and Mexican Boundary Survey.† In 1892-93 the writer made most of the actual stadia measurements on the tangent or boundary line from El Paso to Yuma, Ariz., besides sharing in the topographic traverses in the same region. In the 20 years which have elapsed since this work was done, he has given a good deal of thought to this subject in connection with both his instruction in topographic surveying at the University of Wisconsin, and also in certain stadia surveys of Wisconsin's most important lakes and rivers, some of which are described later. This work included the running of more than 2 000 miles of stadia traverses, and was secured under a great variety of climatic and other conditions, and for a variety of purposes. This experience has often illustrated the fact that there are many ways in which to make stadia measurements (as well as steel tape measurements), all depending on the character of the work and the accuracy required. Stadia measurements, in fact, should mean many things to all men, not one thing to some men.

* Continued from January, 1914, *Proceedings*.

† "Topography on the Survey of the Mexico-United States Boundary," by J. L. Van Ornum, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. XXXIV, p. 259.

Mr. Smith.

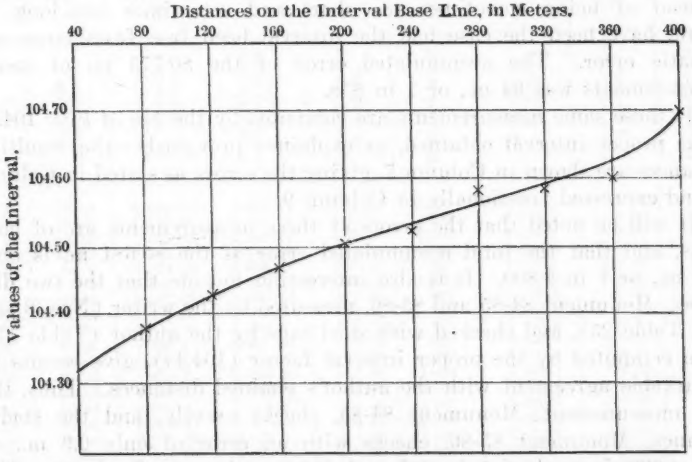
The paper includes certain criticisms of the Barlow International Boundary work. The reader must not forget that this field work, as a matter of fact, was completed more than 20 years ago. In what line of engineering endeavor would it not be possible to criticize the work of two decades ago, in the light of present knowledge? It would be difficult to show that this work was not the most wisely planned topographic work of its day. The country covered included hundreds of miles of trackless deserts interspersed with scores of mountain ranges, all uninhabited and in most part devoid of water. In the Rio Grande boundary work, such extremes were not present, and, in general, conditions were much more favorable for accurate work.

The writer agrees thoroughly with Mr. Follett that adjustable stadia wires are "a delusion and a snare", also that rod levels for keeping the rod plumb are generally unnecessary, but he cannot agree with his statements regarding the general needlessness of an interval determination. It would be a very unimportant piece of work indeed on which the writer would use a steel tape without testing its length as reported by the dealer. The testing of the wire interval of a transit supplies the same information as the testing of the steel tape. So far as concerns the need of either test, it must be admitted that the wire interval is much more likely to change in the field than is the length of a steel tape. The author advocates sending the transit from the field to the manufacturer for readjustment of the interval whenever changes make this necessary.

The writer knows of engineers who send their transits to the instrument maker for even the ordinary adjustment, but he does not favor such a practice. When the adjustments and calibrations of a transit are made in the field by the engineer who uses such instrument, better results may generally be expected than if such adjustments and calibrations are made by some unknown mechanician in a distant city. Moreover, the danger of changes during transportation is always to be considered.

A careful examination of the fifty transits belonging to the Surveying Department of the University of Wisconsin, as well as a score of other instruments with which the writer at some time has been familiar, discloses the fact that only rarely has the stadia interval been found to be even approximately 100. In fact, even if the stadia wires were exactly one-one hundredth part of the focal length of the lens in the factory, one could not be certain that they would intercept 1 ft. on the rod for every 100 ft. of distance when used under vastly different circumstances in the field. This is not a matter of theory with the writer, but of frequent and accurate determination. He feels more certain to-day than he did 20 years ago that the general rule regarding the calibration of instruments applies equally well to the stadia interval; namely, that such calibrations, as far as con-

venient, should be made under the same circumstances as those to be met in the field work. Mr. Follett does not seem to think such precautions likely to result in more accurate work, and quotes certain stadia measurement made by the writer in 1892 to prove his point. It is now proposed to use these same stadia measurements, together with seventeen others, all checked by triangulation and steel tape measurements, to show that had not less but more care been taken in one important particular, a much higher accuracy would have resulted. Mr. Smith.



CHARACTERISTIC INTERVAL CURVE, U.S.-MEXICAN BOUNDARY LINE, 1892-93.
FIG. 4.

In determining the stadia interval the method was to read the rods every 40 m. on a measured base line 400 m. long. A single determination of the interval was thus secured at each 40-m. point. These values are platted as the ordinates and the distances as abscissas of a curve, which, much generalized, is shown in Fig. 4. The adopted or working value of the interval was the average of all the ten values obtained at the various base distances. On account of the systematic differences in these partial intervals, this method would be correct only in case the stadia readings of the later field measurements were distributed approximately over the same range in distance as those of the interval determination. Now, in measuring the boundary line, rod readings at greater distances than 270 m. were not taken. The writer has reviewed the original field books concerned, and has found that had the computations for the stadia interval been restricted to the corresponding distance limit (270 m.), the resulting working interval would have been 104.44 instead of 104.60. This method was not followed at the time the measurements were made because its necessity then was not realized.

Mr. Smith.

When preparing their report, 2 years later (1895), this feature of determining an interval was discussed and approved by the U. S. Commissioners. Table 25 is a record, which was checked by triangulation or steel tape measurements, of the writer's boundary stadia measurements and taken from page 235 of the U. S. Commissioner's report. A study of this table discloses the fact that the sign of the error of every stadia measurement checked is positive, that is, the distances, as measured by the stadia, were in every case too long, instead of being sometimes too short and sometimes too long, as would have been the case had the interval been free from large systematic error. The accumulated error of the 80 775 m. of stadia measurements was 94 m., or 1 in 858.

If these same measurements are computed by the use of $k = 104.44$ —the proper interval obtained, as explained previously—the resulting distances are shown in Column 7, giving the errors as stated in Column 8, and expressed fractionally in Column 9.

It will be noted that the errors of these measurements are of both signs, and that the total accumulated error of the 80 681 m. is only 28.8 m., or 1 in 2 800. It is also interesting to note that the two distances, Monument 84-85 and 85-86, measured by the writer (Nos. 8 and 9 of Table 25), and checked with steel tape by the author (Table 17), when computed by the proper interval factor (104.44), give results in remarkable agreement with the author's chained distances. Thus, the first measurement, Monument 84-85, checks exactly, and the stadia distance, Monument 85-86, checks with an error of only 0.9 m., or 1 in 4 930, instead of 1 in 657 and 756, as given in Table 17. The fact that the interval factor, 104.44, was computed from the actual field notes and published 15 years before the author's steel-tape measurements were made, should prove the entire reliability and independence of the writer's statements and comparisons. This work emphasizes the fact that an accurate stadia interval must be secured in order to prevent large systematic errors. The greatest advantage of stadia measurements—the certain approximate balancing of the accidental errors—is neutralized if large systematic errors are allowed to enter.

The measurements given in Table 25 are less than 10% of the boundary measurements made by the writer, and it was the general belief that they constituted the poorest work of the 800 000 m. In fact, they were checked over with the tape because of the large discrepancies from the Mexican measurements.

The writer shares the opinion, expressed in Mr. W. N. Brown's discussion, that the author under-estimates the accuracy with which stadia measurements may be made. Moreover, this greater accuracy can be secured without the expense of much labor or time. The office work of preparing an interval table* does not require more than an

* Johnson and Smith's "Surveying," pp. 76-78.

hour, and with such a table the day's field notes can be reduced in 15 min. The time taken for an interval determination will be a small part of that involved in sending the transit to the instrument maker for adjustment of the wires. Mr. Smith.

* Stadia measurements referred to by the author in Table 17.

Greater accuracy in the stadia measurements may involve the saving of expensive control.

This is well illustrated by the methods adopted by the Wisconsin Water-Power Survey, a co-operative survey between the State and the U. S. Geological Survey.*

The specifications for this work were made nominally by the U. S. Geological Survey, but the writer was permitted to make several important changes which either added to the value of the work or greatly reduced its cost. One modification in the field work was the substitution of the magnetic needle for the control of all directions, the magnetic declination being frequently determined from Polaris observations. All distances were read by stadia and water levels; shore lines and contours were determined either by level or vertical-

* This work was done in 1906–07.

Mr. Smith.

angle readings. Only every other turning point was occupied by the transit, a method which increased the speed by about 33 per cent.

Such horizontal control as was needed for the purposes of a preliminary survey was secured by checking on the section lines where they crossed the river, a feature which had the additional advantage of showing also the ownership of the riparian rights.

The vertical control was secured by running Wye-level lines and establishing permanent bench-marks on or near the river at intervals of about 2 miles, 400 miles of such levels being run at a total expense of $1 277. The unit cost of these levels varied from $2.16 per mile in a settled country with good roads to $4.85 per mile in a region devoid of roads and settlements. The instrument men on this work were junior civil engineering students at the University of Wisconsin.

As little on the subject of the accuracy of transit leveling has appeared in engineering literature, it may be of interest to examine in detail the accuracy of this work, which is shown in Tables 26, 27, and 28. In judging its accuracy, it should be remembered that the average turning-point distance was about 1 500 ft., and that the young men had had very little instrumental experience. The sensibility of the level corresponded to $\frac{1}{10}$ in. = 15″ of arc. The transits had object glasses $1\frac{1}{4}$ in. in diameter and the eye-piece magnified 24 times.

					Average.		0.15	

Table 26 shows that the largest error per mile on any stretch of the Black River Survey was 0.33 ft., and that the average error per mile was 0.15 ft. These errors, however, compensated to a remarkable extent, so that at the end of 10, 20, 31, 41, 51, and 58 miles the corresponding accumulative errors were only 0.03, 0.05, 0.04, 0.06, 0.04.

and 0.009 ft. per mile. The same engineer, Mr. Victor Reineking, next surveyed the Flambeau River with even better results, as will be seen from Table 27. Mr. Smith.

13	3.5	0.81	.....	+0.81	0.23	+1.01	0.02	48.9
14	1.3	.....	0.08	−0.08	0.02	+0.98	0.02	50.2

The largest error was 0.22 ft. per mile, the average being 0.09 ft. per mile. Of the 31 checks, 14 show minus and 17 plus errors. This compensation, as shown in Table 27, is truly surprising. The total accumulative error at the end of the 92.3 miles was only 0.26 ft. or 0.027 ft. per mile.

Table 28 gives the results of transit leveling on the Wisconsin River Survey. Because of a misunderstanding of directions, the leveling on the first 32.7 miles of river was done by reading vertical angles, with the result that the largest errors are found in this stretch. In the remaining 168 miles of levels, the average error per mile is 0.04 ft., and the total accumulative error on the 200 miles is 0.57 ft.

NOTE:—"Lost time" includes Sundays, holidays, and stormy weather. Miscellaneous

Mr. Smith.

The 82 miles of transit levels run on the Peshtigo River were, for the most part, in rough, rocky, and heavily timbered country. The largest error per mile in any stretch was 0.23 ft., the smallest was 0.02 ft., with an average of 0.09 ft. The largest accumulated error was 1.64 ft., at a point 33 miles from the beginning. The accumulative error per mile gradually decreased from 0.09 ft. near the beginning to only 0.02 ft. at the end of the 82 miles.

It is perfectly manifest, from this record of 400 miles of transit levels, that for general preliminary surveys transit levels are amply sufficient without Wye-level control. Such omission would have reduced the cost of the survey by an average of $3.24 per mile.

Very careful records of the most important elements of cost data were kept, and are given in Tables 30 and 31. These elements, together with the costs of supervision, are assembled in Table 31. The greater cost of the Flambeau River work was due to working in the winter on the ice. The winter happened to be one of unusual severity, with very low temperatures and many deep snows. This resulted in the loss of about 30 work days, which increased the cost by $3.50 per mile of survey.

The surveys were mapped on a scale of 1 000 ft. to 1 in., and published by the U. S. Geological Survey on a scale of 2 000 ft. to 1 in. It will be noted that the total cost of 487 miles of river surveys, including both field and office expenses, was $4 798.30, or only $9.85 per mile for both profile and plan with land sections. This work furnishes a good example of the adaptability of the transit and stadia method.

Sir WILLIAM HENRY WHITE, Hon. M. Am. Soc. C. E.*

DIED FEBRUARY 27TH, 1913.

William Henry White, the youngest child of Richard and Jane (Matthews) White, was born at Devonport, England, on February 2d, 1845. He attended the local schools until March, 1859, when, at the age of fourteen, he was apprenticed at the Royal Naval Dockyard. In addition to his practical work, he attended the Dockyard School, maintained by the Admiralty as a part of the technical training of its apprentices, where he showed his ability by winning an Admiralty Scholarship in 1863.

It was during this time that propulsion by steam was being substituted for sails, and sailing vessels were being reconstructed as screw-propellers. The use of iron in place of wood for the hulls of vessels was also being introduced, and young White had the advantage of combining practical work with the preparation of designs, the results of which were clearly shown in his highly responsible work of later years.

In 1864, the Admiralty, at the urgent request of the Institution of Naval Architects, established the Royal School of Naval Architecture at South Kensington, in connection with the Science and Art Department. This school, which was instituted in order that students in naval architecture might take advanced courses in that science, was afterward merged into the Royal Naval College at Greenwich. Sir William was one of the first students received at this newly founded college, taking first place at his entrance examinations in 1864, which standing he maintained during his three years of attendance. He was graduated in 1867, with the highest honors, as a Fellow (first-class). In 1870 he was made Professor of Naval Architecture at this school, which position he held until 1881. This work was in addition to his duties at the Admiralty. Among his pupils during this period were men who afterward became chief constructors and naval architects in the various navies of the world, and it was largely due to his influence that the school's high standing was acquired and maintained.

Immediately after his graduation from the Royal School of Naval Architecture, Sir William entered the Admiralty as Private Secretary to Sir Edward Reed, Chief Constructor, being engaged in the solution of scientific problems in naval architecture, etc. It was while he oc-

* Memoir prepared by the Secretary from information on file at the Society House.

cupied this position that he was brought directly in touch with the design of armored vessels which were then a new invention, thus adding to his experience as a designer and constructor.

In 1870, on the resignation of Sir Edward Reed and the appointment of a Commission to continue his work, of which Sir Nathaniel Barnaby was Temporary President, Sir William was made Professional Secretary to the Commission. In this position, and with the aid of his life-long friend, the late Mr. William John, he had charge of, and carried out, numerous experimental inquiries in regard to the stability of ships for the Commission appointed to investigate the capsizing of the ironclad *Captain*, in the Bay of Biscay. The results of these inquiries were embodied in a paper* on the subject presented before the Institution of Naval Architects, which greatly advanced the science of ship design.

In 1875, Sir William was promoted to the rank of Assistant Constructor, and, in 1881, he was advanced to that of Chief Constructor. While in this position he effected the organization of all the trained architects in the Admiralty into one corps—the Royal Corps of Naval Constructors—which organization has proved of great service to the British Navy. In 1883, when Sir William Armstrong was establishing his great shipyard at Elswick, England, he offered to Sir William the difficult feat of organizing and directing the Warship Building Department. While in this position he made designs for naval vessels for Austria, Italy, Japan, China, and Spain, and had charge of the construction of several vessels for the British Navy, among which was the *Victoria* which, in 1893, was sunk in the Mediterranean by a collision, with great loss of life.

In 1885, Sir Nathaniel Barnaby resigned his position at the Admiralty on account of ill-health, and on his recommendation, Sir William, having been released from his contract with Sir William Armstrong, Mitchell and Company, was appointed Director of Naval Construction and Assistant Controller of the Navy, which position he held until February, 1902, when he also was compelled to resign on account of ill-health.

Sir William began his work as Director of Naval Construction at the Admiralty at the beginning of a period of expansion in British Naval affairs. Prior to that time no uniformity in the vessels of the fleet had been attempted, and the reorganization of the administrative and operative departments was demanded. The Northbrooke programme, which comprised the carrying out of the construction of a number of new ships and the rapid completion of those already begun, was his first task, and the work was accomplished so expeditiously that when the Naval Defence Act of 1889 was passed, providing for

* "The Calculation of the Stability of Ships, and Some Matters of Interest Connected Therewith," by W. H. White and W. John, *Transactions*, Inst. of Naval Archts., Vol. XII, p. 77.

the construction of 70 ships at a cost of £22 000 000, sterling, Sir William had a chance to carry out his idea of homogeneity in a fleet, namely, ships bearing a distinct relation to each other and to the fleet as a whole. The Spencer programme of 1894 and the Goschen programme of 1896, the latter comprising the construction of the first dreadnought of the British Navy, were also carried out under his supervision. The development of the torpedo boat and the torpedo-boat destroyer was due to his skill, and he also designed the river gunboats built for the Nile Expedition under Lord Kitchener. When he retired in 1902, he had had responsible charge of the design and construction of 245 vessels, valued at about £100 000 000, sterling. All this vast work was done under constantly changing conditions of material, type, size, speed, armament, etc., and to him may be attributed the introduction of several innovations in British warships, notably that of water-tube boilers and the use of oil fuel for firing boilers. He had entered the Naval Service before the first real ironclad was ordered, and had seen the Navy develop from one of wooden ships to the present-day steel dreadnought.

He was awarded a C. B. in 1891 and a K. C. B. in 1895, and on his retirement from the Admiralty in 1902, Parliament voted him a special grant for "exceptional services to the Navy."

After a rest and the recovery of his health, Sir William began practice as a Consulting Naval Architect, and was engaged on many important works. He was a member of the Cunard Commission which decided the type of machinery for the *Lusitania* and the *Mauretania;* a Director of the firm of Swan, Hunter, and Wigham Richardson, Limited, the builders of the *Mauretania,* during her construction; a Director of the Parsons Marine Turbine Company; and a Director of the Grand Trunk Railway Company after that Company became the owner of steamships. He designed steamers with geared turbines for service between India and Ceylon, and was a Member of the Government Commission to investigate the question of load lines of merchant ships.

On February 27th, 1913, Sir William suffered a paralytic stroke at his offices in Westminster, and died the same day at Westminster Hospital to which he had been removed.

He was twice married, his first wife having been Miss Alice Martin who died in 1886. In 1890, he was married to Miss Annie Marshall who, with three sons, all of whom are officers in the British Navy, and one daughter, survives him.

Sir William was a frequent contributor to technical and engineering journals and to the publications of technical and scientific societies. He was also the author of several books, his "Manual of Naval Architecture" and "Treatise on Shipbuilding" having become classics, the former being translated into German, Italian, Russian, and Spanish.

His most notable contributions were made to the *Transactions* of the Institution of Naval Architects, the best known being the papers on the stability of ships (already referred to), the rolling of sailing ships, and the effect of bilge keels on rolling, and his description of the design of the battleship *Royal Sovereign*. That his versatility was not confined to engineering, but extended over a wide range of subjects, is shown by his contributions to various newspapers and magazines.

He was always greatly interested in questions of engineering and technical education, owing, perhaps, to the difficulties he experienced in acquiring his own training. He was Chairman of the Committee on the Education and Training of Engineers, appointed by the Institution of Civil Engineers in 1903, and was also a member of the Governing Body of the Imperial College of Science and Technology.

Sir William was connected with many engineering and scientific societies and associations, to which he was always ready to give advice and assistance, and many of these had honored him with offices of distinction. He was a Fellow of the Royal Society; Honorary Vice-President of the Institution of Naval Architects; Past-President of the Institutions of Civil Engineers, Mechanical Engineers, Marine Engineers, Junior Engineers, and the Institute of Metals; President-Elect of the British Association for the Advancement of Science, having been President of the Mechanical Science Section. He was also an Honorary Member of many other British and foreign technical societies, including the American Society of Mechanical Engineers and the Society of Naval Architects and Marine Engineers.

In 1911 he was awarded the John Fritz Medal by a Board of Award appointed by the four leading American engineering societies—Civil, Mining, Mechanical and Electrical—for "notable achievements in naval architecture." He had also received honorary degrees from many colleges and universities, among which were LL.D. from Glasgow, D. Sc. from Cambridge, Durham, and Columbia (New York City) Universities, and D. Eng. from Sheffield. He also belonged to the Athenæum and British Empire Clubs.

In regard to his personal characteristics, the following* was written by one who had been on terms of close friendship with him for more than 30 years:

"He was beyond compare the straightest and most generous man alive. He was, without exception, the most remarkable man I have known, and as honest as the day. From the start he had never a soul to help him, but achieved distinction by his own ability and industry. A foreign government made overtures to him to superintend the total reconstruction of its then somewhat infirm war flotilla. White, with that fine sense of honour which was inseparable from the man, re-

The Times (London), February 28th, 1913.

fused a most lucrative offer because he considered the value he could return for the great monetary payment held out to him, could only have been acquired by his intimate knowledge gained in the service of our Admiralty. The amount of work that he did without repayment in those educational institutions which are bringing forward the most intelligent men of the new generation, was beyond compare. His self-negation, accurate knowledge, and charming manner extraordinarily enhanced by a great gift of description, made him such a professor of scientific and applied mechanics as the world has seldom seen."

Sir William Henry White was elected an Honorary Member of the American Society of Civil Engineers on December 16th, 1904.

HORACE GUY MERRICK, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 30TH, 1913.

Horace Guy Merrick was born at Libertyville, Ill., on January 29th, 1879. His family moved to Manistee, Mich., when he was quite young.

Mr. Merrick's education began in the public schools at Manistee, and he was graduated from the High School of that place in 1898. During the next three years he was engaged on various public works in Michigan. In 1901 he entered the University of Michigan, from which institution he was graduated in 1905, with the degree of B. S. in Civil Engineering.

After his graduation he was employed by the United States Government as Junior Engineer on the survey of the Great Lakes until May, 1907, when he was transferred to the work of improving the Upper Mississippi River, with headquarters at La Crosse, Wis. He remained on this work until his death.

In 1913, Mr. Merrick took the examination before the United States Civil Service Board for registration and promotion to Assistant Engineer, and passed with much credit.

He was an energetic and capable civil engineer, and was held in high esteem by his superior officers. He felt no wish to become conspicuous, professionally or otherwise, shrinking from notice rather than courting it. He always under-estimated his own ability, and worked zealously, intelligently, and successfully from love of his Profession.

Mr. Merrick was elected an Associate Member of the American Society of Civil Engineers on May 7th, 1913. He was also a member of the Wisconsin Society of Civil Engineers.

THE GAUGE OF RAILWAYS, WITH PARTICULAR REFERENCE TO THOSE OF SOUTHERN SOUTH AMERICA.

By F. Lavis, M. Am. Soc. C. E.

To be Presented April 1st, 1914.

Synopsis.

The question of the gauge of railways, though not important in the United States, where it was solved many years ago by the adoption of 4 ft. 8½ in. as a standard, is a live issue in South and Central America, where there are lines of nine different gauges, those most in use being 1 meter, 4 ft. 8½ in., and 5 ft. 6 in. During a recent visit to the Argentine the writer made an investigation of this subject, some of the results of which are embodied in this paper.

The railways of South America have been most largely developed, thus far, by European capital and engineers, but, owing to the changed conditions which have placed, or will soon place, the United States in the position of an importer of food supplies and a seeker for markets for its manufactured products, it seems evident that we must take a much greater and more intimate interest in South and Central American affairs. This question of gauge, therefore, is one which may interest many American engineers in the not far distant future.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

The subject is treated in the order and under the several different headings mentioned below, the conclusions being briefly summarized as follows:

Curvature.—Within the limits of the practical operation of railroads, any radius curvature which is feasible on meter gauge is as practical on 4 ft. 8½-in. or even 5 ft. 6-in.

Gradients.—The working of trains on steep gradients is not affected by gauge, except in so far as the narrow-gauge cuts down the locomotive capacity and is, therefore, at a great disadvantage.

Location.—In view of the above, the narrow-gauge (3 ft. 0-in. to 3 ft. 6-in.) does not permit better adaptability of the alignment to the conformation of the ground.

Cost of Construction.—This is so little more for 4 ft. 8½-in. than for 3 ft. 0-in., or 3 ft. 6-in., as to be more than counterbalanced by economy in operation.

Speed.—This is an important feature in railway operation, which is adversely affected by narrow-gauge.

Stability.—The relative stability of narrow-gauge trains in motion is much less than that of trains on medium- or broad-gauge, and, consequently, high speeds are impractical on narrow-gauge, and may be dangerous.

Track Stresses.—Much higher track stresses are produced on the narrow-gauge. There is greater impact, and therefore more difficulty in maintaining track on narrow- than on broad-gauge.

Rolling Stock—Cars.—The greater width in proportion to the gauge of narrow-gauge cars is considered a necessary evil rather than an advantage, and it is shown that there is probably no advantage to be gained by making the broad (5 ft. 6-in.) gauge cars any wider than they are at present. In the matter of passenger cars, the narrow-gauge is at a decided disadvantage both as to cost per unit of accommodation and in dead weight per passenger. In freight cars there is little difference in cost within the limits of size possible on the narrow-gauge, though cars of twice the capacity are available for medium- or broad-gauge. The increase in weight of modern freight trains, in order to decrease the cost of operation has made heavier draft rigging necessary, thus tending to increase the proportion of dead to paying load to a much greater extent on cars of small capacity than on the larger ones, than has been the case heretofore.

Locomotives.—The cost per unit of capacity of locomotives is about the same for each gauge, up to the limit of the narrow-gauge, which limit for all types is about half that of the 4 ft. 8½-in. or 5 ft. 6-in. There is an economy in the use of heavier types of locomotives not available for the narrow-gauge, and the use of cars of large capacity is a necessity for cheap transportation.

Train Resistance.—The train resistance is decreased by the use of larger units.

Capacity.—Figures are given tending to show that the relative traffic capacity of narrow-gauge lines is not more than half that of medium- or broad-gauge.

Heavier Engines and Trains.—There is a general discussion showing the part played by the increase of train loads in reducing costs in the United States.

Cost of Operation.—The ton-mile costs on both Indian and Australian railways, as well as those in the Argentine, are less on the medium- and broad-gauge than on the narrow-gauge, although the train-mile costs are often higher.

The lowest ton-mile costs on any railway in the Argentine are more than twice as high as they are in the United States. The saving in cost of operation, due to the use of larger cars and heavier trains, would be considerable, and would in itself go a long way toward meeting the interest charge on the additional cost of the wider gauge.

Cost of Maintenance.—Maintenance of way probably costs more per traffic unit on narrow- than on medium- or broad-gauge on any but lines of very light traffic.

Maintenance of equipment should be less on medium- or broad-gauge by reason of the larger capacity and, consequently, lesser number of locomotives and vehicles, provided there is business to warrant the use of these larger units.

Need of Efficient Transportation Machine.—The necessity of an efficient transportation machine to develop the country properly is pointed out, as well as the part played by the railways in developing the United States, the country most nearly comparable with Brazil and the Argentine.

There are two appendices: Appendix A gives a short account of the history of the gauge question in the United States, with some notes of its present status in India, Australia, South Africa, etc. Appendix

B contains a general description of the topography, physical characteristics, and business conditions of Southern South America, and the development and present situation of its railways.

It is shown that the development and growth of this area is most nearly comparable to that of the United States, and for its exploitation a transportation machine not less efficient than that of the railways of this country is necessary. The growth of the railways of the Argentine is reviewed in some detail, showing their development within the past few years from a series of little local lines which were not much affected by the gauge to a series of fairly extensive systems, where the distances to be covered and the necessary weights of trains to be handled are showing the deficiencies of the narrow-gauge. This growth, and the increasing distances from the seaboard to new areas being opened up, all point to the need of the most efficient transportation system for its proper development.

It is believed to be shown that the narrow-gauge is an inferior transportation machine; that, as far as new lines are concerned, there is little saving and no economy in their construction, and that this gauge is inadequate for the development of areas as large as those under consideration; that the 5 ft. 6-in. gauge offers little if any advantage over the 4 ft. 8½-in.; that, taken altogether, the latter, which has been adopted as the standard in North America, Europe, Western Asia, and Australia, is best adapted to the development of this region; that new lines should be built to this gauge, and that it is economically sound to make the expenditures necessary to change the existing narrow-gauge lines to this standard.

It is pointed out that the cost of changing the gauge of the existing lines cannot be considered entirely alone, and figures are presented showing the estimated additional cost of the whole system of standard-gauge lines at the end of 20 years. The figures tend to show that, including the cost of changing the existing narrow-gauge lines, and taking into account the additional cost of building the new lines of standard- instead of narrow-gauge, that the final standard-gauge system will have cost about $5 000 per km. more than if the narrow-gauge is perpetuated, and that, under certain assumptions, such as the greater need of stone ballast, the earlier requirements of double track, etc., on the narrow-gauge, this estimate would probably be materially reduced.

Figures are given, which, taking into consideration only those items which are readily estimated in money values, tend to show that the saving in cost of operation would be sufficient to cover the interest charges on the additional cost, and, besides all this, there is the fact that the narrow-gauge is an inferior transportation machine not adapted to the development of the transportation system of a continent.

The question of the gauge of railways was settled in North America many years ago, and, so far as regards this country, or even Europe, any discussion of the matter is purely academic. The development of railway transportation in the rest of the world, however, except in certain limited sections, is as yet in its infancy, the only sections of the vast area lying to the south of the United States where any substantial progress has been made being parts of the Argentine, Southern Brazil, Chile, Peru and Mexico, and these by lines of many different gauges, varying from 2 ft. 6 in. to 5 ft. 6 in.

The writer was asked recently to make a study and report on the gauge question, as affecting the future development of the Argentine, and, as the subject is a vital one in all countries south of the United States —or perhaps more correctly south of Mexico—it is thought that the presentation of those parts of the report which are of general interest may not be untimely. This, perhaps, is especially the case now, when the United States is beginning to be forced to look for foreign markets for its manufactures, with South America as the natural field for its enterprise, and when, consequently, the interest which American engineers are likely to have in this development may be of considerable importance.

The probable future growth of the southern part of South America may be fairly comparable with that of the United States during the past 50 years. The importance of the railways as a factor in this latter has been well stated by M. Colson, an eminent French engineer,* who points out how necessary cheap, efficient railway service is in the development of new countries. It is for this reason that American railway engineers, who have been intimately connected with the railway development of their own country, should be interested in the future of South America, as their own experience should enable them to be among the best judges of the necessities of countries which, like

* See p. 614.

those in southern South America, are entering on an era of expansion comparable only to that of their own.

Europe, like the United States, long ago adopted the 4 ft. 8½-in. gauge as the standard, but the gauge question is still being actively discussed in India, where the standard is 5 ft. 6 in., with a considerable mileage 1 m. and less. Australia, where the gauges are 5 ft. 3 in., 4 ft. 8½ in., and 3 ft. 6 in., according to recent reports, has only recently decided to unify them and adopt 4 ft. 8½ in. as the standard; and Africa, unfortunately, seems to be definitely committed to what one eminent British engineer recently described as "the miserable 3 ft. 6 in. gauge."* China has adopted 4 ft. 8½ in., the Trans-Siberian Railway is 5 ft. 0 in., the South Manchurian Railway and the Korean railways are 4 ft. 8½ in., and the Japanese railways are mostly 3 ft. 6 in., with some 2 ft. 6 in., though it is stated that these latter are to be changed to 4 ft. 8½ in. as the result of their failure to meet the emergency caused by the Russian war.

It is, perhaps, true that the possible use of railways for war purposes can hardly be considered as an important economic factor in determining the basis on which they shall be designed—at least it is hardly as important in America, either North or South, as it might be in Europe or Asia—still the experience of the Japanese, as well as the English in India, tends to show the inferiority of the narrow gauge for transportation, especially in an emergency. In countries growing as rapidly as those of southern South America, this really means that it will not be long before the narrow-gauge lines will reach the same state of inadequacy to meet the natural development and growth of a new country as they have wherever they have been submitted to the emergency test of war.†

This is already apparent on some of the lines in the Argentine, and, in Brazil, the Paulista Railway Company is now reconstructing its narrow-gauge lines west of Rio Claro to 5 ft. 3 in., as it cannot handle the business offered, although the heaviest narrow-gauge equipment, both locomotives and rolling stock, is being used. Some further notes in regard to the experience of other countries with lines of various gauges are given in Appendix A.

* "The Railway Gauges of India," by Sir Frederick Robert Upton, *Minutes of Proceedings*, Inst. C. E., Vol. CLXIV, p. 196.

† See, also, p. 580.

Some matters treated in this paper are, perhaps, not strictly technical, or may be considered somewhat elementary; but, as this subject is of interest to laymen as well as to engineers, and as the latter may often be called on to present the arguments, for or against the adoption of any particular gauge, to governments, the public, or investors, it has been thought desirable to include them all. In regard to some phases of the technical aspect of the subject, also, certain matters have been included which have long been accepted as almost axiomatic by engineers in North America, though it is the writer's experience that they are not always so accepted elsewhere.

The lengths of the lines of various gauges in the countries to the south of Mexico (which latter is practically all standard (4 ft. 8½ in.) gauge) are shown in Table 1.* Generally throughout the paper, when speaking of narrow gauge, it will be considered to include the 3 ft., 1 m. and 3 ft. 6 in. The medium or standard gauge is the United States, 4 ft. 8½ in. The broad is 5 ft. 3 in. and 5 ft. 6 in. It may be noted that the standard is 5 ft. 3 in. on the Irish Railways, and 5 ft. 6 in. on the Indian Railways.

Appendix A contains a table showing the length of the lines of the various gauges throughout the world, the total length of each gauge being, approximately:

Broad	145 300 kilometers	=	90 086 miles.
Medium	727 799 "	=	451 235 "
Narrow	183 416 "	=	113 719 "

The accompanying map, Plate I, shows the railway lines of Southern Brazil, Uruguay, Paraguay, the Argentine, and parts of Chile, Peru, and Bolivia, and indicates the extent of each of the three gauges and their location. Speaking generally, it will be noted that the Brazilian railways are nearly all narrow-gauge, with the exception of parts of the important lines of the São Paulo and Paulista Railways, running into the interior from Santos, the line of the Central Railway of Brazil connecting São Paulo and Rio, and a line from this latter point into the interior, all of these being 5 ft. 3 in. The medium-gauge (4 ft. 8½ in.) lines occupy the strip of country between Brazil and the Parana River, including the whole of Uruguay and Paraguay, and the Argentine Provinces of Entre Rios and Corrientes. In the Argentine, the most intensively developed section—that lying between the City of Bahia Blanca on the south, and the Cities of Rosario, Cordoba, and Mendoza on the north—is occupied principally by the broad-gauge, the narrow-gauge railways occupying the section to the north of this, though in the zone between Buenos Aires, Mendoza, Cordoba, and Santa Fe, the territory is divided between the two, the broad-gauge having somewhat the advantage. Chile and Bolivia seem to be committed to the meter-gauge for all new lines, the former, however, has seven distinct gauges, and in Bolivia the Antofogasta Railway is 2 ft. 6 in. Peru, although fully as mountainous as any part of Chile or Bolivia, has practically adopted the 4 ft. 8½ in. gauge, its lines being among the highest in the world, with several hundred miles at elevations of more than 10 000 ft. above sea level, the famous Oroya Railway reaching 15 583 ft., the highest main line in the world. North of Peru the lines are nearly all narrow-gauge until Mexico is reached, the single exception being the Panama Railway, which is 5 ft.

A more detailed description of the railways of the Argentine, and

UNIV. OF MICH.

of the climatic, topographical, general physical conditions, and business of the southern part of South America is given in Appendix B.

Effect of Gauge on Location.—It is quite generally supposed that the narrow-gauge is better adapted to mountain location than the wide-gauge, because it permits the use of sharper curves and steeper gradients. Within the limits of practical railroad operation, this supposition is not warranted by the facts, when comparing meter and 4 ft. 8½ in., and there is very little difference with regard to 5 ft. 6 in.

Curvature.—Within the limits of curvature allowed on the meter-gauge roads of the Argentine, that is, with a minimum radius of 490 ft. (150 m.), it is quite possible to operate 5 ft. 6 in. gauge rolling stock which, as a matter of fact, is handled every day in long trains with side-buffers in the yards at the terminals over No. 8 turnouts which have a radius of about 485 ft. (148 m.), and over main-line, No. 10 turnouts with a radius of 780 ft. (241 m.). There are said to be branches on some of the broad-gauge roads with curves of 490 ft. (150 m.) radius; and the line to the power-station at Lules, near Tucuman, over which broad-gauge trains are operated, has curves of less radius than this. The Southern has just located a line with curves of 656 ft. (200 m.) radius across the mountains beyond Neuquen.

The idea still exists in the minds of many people that trains can actually pass sharper curves on a narrow-gauge than on a broad-gauge. "Reduced to absurdity," this, of course, is so, but within the limits of practical railroad operation, on such lines as those under consideration, it is not, and there can be no question that trains of 5 ft. 6 in. gauge with center couplings can pass around any curves which it is practical to operate on meter-gauge lines built to do business. Sharp curvature limits the speed of trains, and in this respect it imposes quite as much, probably greater, limitation on narrow-gauge trains by reason of their lesser stability than it does on broad-gauge trains. The fallacy that sharper curves are not possible on broad-gauge lines probably arose in the early days, before the swiveling truck was introduced. The possible adaptability of the broader or medium gauge to the conformation of the ground has also quite generally been confused by the assumption that, because the gauge was broader the whole road and rolling stock must be of heavy construction; that is, with many people the term "light" railways has

been considered synonymous with narrow-gauge, whereas there is no reason that light rails and light rolling stock cannot be used as well on broad-gauge as on narrow. One has only to consider the rolling stock in use on British Railways 25 years ago, or even to a large extent in England to-day, with the little 5-, 8-. and 10-ton wagons, to realize this. The use of sharp curvature is by no means advocated as desirable, as the objections to its use are fully realized, but the objections to sharp curvature are no less on meter-gauge than on the medium or broad.

Properly designed rolling stock is, of course, a necessity in any case. Certain 40-ton shunting engines of the Cordoba Central Railway (meter-gauge) have difficulty in passing curves of 328 ft. (100 m.) radius in the yards, by reason of their stiff frames and long wheel base. The 850 000-lb. Mallets on the Atchison, Topeka and Santa Fe Railroad in the United States (4 ft. 8½ in.) are operated on curves of only slightly greater radius without trouble, and haul trains of standard Pullman equipment, the coaches being from 65 to 75 ft. long.

A locomotive of the Mikado (2-8-2) type, having a total weight of 285 000 lb. (220 000 lb. on drivers), built by the Baldwin Locomotive Works, has just been put in service on the railway of the Woodward Iron Company (4 ft. 8½ in.), on a line with 3% grades and 16° (110 m. radius) curves.

The New York City Elevated Railways (4 ft. 8½ in.) were built about 35 years ago, and are operated on an open steel viaduct over the streets of New York. Nearly a million passengers and about 1 000 trains a day pass over them. They have several curves of 90 to 125 ft. (30 to 40 m.) radius, and have an enviable record for safety, only one accident to a train in which the life of a passenger was lost having occurred in 35 years. These lines were formerly operated by steam, but now by electricity with multiple-unit trains.

On the lines of the New York City Subway (4 ft. 8½ in.), built about 5 years ago, an average of more than 1 000 000 passengers are carried daily. On these lines the radius of many curves is 147 ft., over which cars 51 ft. long and 9 ft. 0½ in. wide, are operated in 10-car trains by the multiple-unit system.

Table 2 contains some data for standard-gauge lines operating (many with a very heavy traffic) over sharp curves and heavy gradients,

some of them, as will be seen, rising to quite high elevations and thus indicating the adaptability of the 4 ft. 8½-in. gauge to mountain location.

TABLE 2.—DATA RELATING TO GRADIENTS, CURVATURE, ETC., ON CERTAIN RAILROADS.

	Grade.	Radius of Curves.		Elevation of summit.	Remarks.
		In feet.	In meters.		
Canadian Pacific	4.49%	498	152	5 299 ft. (1740 m.)	.....
" New Line	2.20%	574	175	.....	Spiral tunnels.
Atchison, Topeka and Santa Fé	3.30%	357	109	7 510 ft. (2 464 m.)	425-ton Mallet.
Denver and Rio Grande	3.80%	498	150	10 433 ft. (3 423 m.)	.....
Colorado Southern	3.50%	193	59	.....	Georgetown loop.
Mersey Tunnel	3.00%	.....	....	.....	.....
Mexican Railway	4.75%	.....	....	.....	.....
Nitrate Railway of Chile	4.00%	298	91	.....	.....
Central Railway of Peru	.....	.....	....	15 865 ft. (5 205 m.)	.....

On the Atchison, Topeka and Santa Fé Railroad—a transcontinental line of very heavy traffic—articulated locomotives of the Mallet type, weighing 425 tons (engine and tender), are in use.

Canadian Pacific: The old 4.49% grade has been operated by adhesion since 1885 up to within a year or two ago, when the spiral tunnels on curves of 574 ft. (175 m.) radius were built and the grade reduced to 2.2 per cent.

On the Nitrate Railway of Chile, 4 ft. 8½-in. gauge, a duplex articulated locomotive hauls 200 tons at 8 miles per hour on 3 to 4% grades (average 2.8%) with curves of 300 ft. radius.

In connection with the location of the line of the Wolgan Valley Railway in Australia, the whole question of gauge and the adaptability of standard (4 ft. 8½ in.) gauge to difficult mountain location was carefully studied by the Chief Engineer, Mr. H. Deane, who reported as follows:

"To bring the line within the region of practicable cost, a ruling grade of 1 in 25 was adopted, with curves of 5 chains [330 ft. = 100 m.] radius. There was no possibility of compensating for curvature, and the 1 in 25 grades occur, therefore, on 5-chain curves, so that the actual ruling grade may be said to be 1 in 22.5 not 1 in 25. A study of plan and section, as well as an inspection on the ground, will show how rigid were the conditions of the problem.

"Bound up with the whole question was that of gauge. Steep grades on a narrow gauge limit the load too much. It was anticipated that when the Company was in full swing, over 1 000 tons of goods would have to be conveyed over the line daily. It was clear, therefore, that the standard gauge must be adopted, especially as the Railway Commissioners had offered to lend their rolling stock if that gauge were not departed from. But how about curvature? it will be said. Was it not excessive? No. Not for the wagons, which were

daily hauled safely over the Camden Railway with its 5-chain curves. But what about locomotives? On the Western line, curves of 8 chains [528 ft. = 173 m.] radius were originally constructed, and had all been cut out because the wear of rails and flanges had been excessive.

"This question had to be solved by looking to the practice of other countries. In New South Wales the locomotives were too stiff. Some other type must be adopted.

"During an extensive journey around the world in 1894, I found numerous curves of 16 degrees, equal to 5½ [363 ft. = 111 m.] chains radius, one curve of 18°, equal to 4.8 chains radius and one of 22°, equal to 4 chains radius, on the Southern Pacific Railway system in the Western United States, and these were traversed by 8-wheeled coupled American locomotives of the Consolidation type. This was rendered possible by providing two of the pairs of wheels with broad, plain treads in place of flanging them. The curves mentioned have now been cut out, but they were worked for many years.

"In 1904 I travelled in a train on the main line of the Canadian Pacific Railway where one curve of 3½ chains [231 ft. = 70 m.] radius exists. All the Company's locomotives traverse this curve.

"On some of the mining branches of the Canadian Pacific Railway, where curves of 5 chains and grades of 4½%, equal to 1 in 22.5, exist, Shay locomotives are used.

"On the Tamaulipas Railway, a scenic line in California, there are curves of 70 and 80 ft. [21 to 25 m.] radius, the traffic being hauled by locomotives of the Shay type.

"On the Kandy Railway in Ceylon there are curves of 5 chains radius, the gauge being 5 ft. 6 in. These are negotiated by locomotives built by Kitson and Company, of Leeds. They are 6-wheeled, coupled, with bogie in front. The middle wheels have thin flanges, considerable play in the axle boxes is allowed, and the connecting rod and side rod pins are barrel shaped, so as to permit of the rods working out of the straight line."

As a further concrete example of the possibilities of operating on standard gauge over mountain lines with heavy gradients and sharp curvature, the following may be cited,* the line being part of one of the Transcontinental routes in the United States:

The main line of the Southern Pacific Railroad in California, between Bakersville and Mojave, a distance of about 68 miles (109 km.), is single track, with maximum grades of 2.2%, uncompensated against traffic both ways, and 10° 20′ (555 ft. = 169 m. radius) curves. There is one continuous curve with a total central angle of 566°, nearly all of which has a radius of less than 600 ft. (180 m.), 18 tunnels

* *Railway Age Gazette*, July 25th. 1913.

with a total length of 8 115 ft. (2 473 m.) and about 4 000 ft. (1 219 m.) of bridging. The summit is 4 025 ft. (1 227 m.) above sea level.

The engines used on this line are as follows:

Passenger service, Mogul (2-6-0) type:

Total weight of engine	166 320 lb.
" " on drivers	144 120 "
Tractive effort	33 320 "

Helper engines, Consolidated (2-8-0) type:

Total weight of engine	208 000 lb.
" " on drivers	187 000 "
Tractive effort	43 305 "

Freight engines, Mallet (2-8-8-2) type:

Total weight of engine	435 800 lb.
" " on drivers	401 000 "
Tractive effort	94 880 "

On a single day in January, 1913, 36 trains passed over this section, of which 16 were passenger trains handling 110 passenger cars, 6 305 tons, and 20 freight trains handling 886 cars, 30 725 tons, a total of 36 trains, 996 cars, 37 030 tons. So that, although sharp curvature is not by any means advocated as desirable, it can be shown that where the exigencies of the topography demand its use, standard-gauge equipment can be operated on it quite as well as on meter-gauge, and the possibilities of reducing operating costs by the use of larger engines far outweigh any small economies in the first cost of narrow-gauge by reason of slightly decreased width of roadbed and shorter ties.

Gradients.—As regards gradients, of course, the gauge makes no difference, the same power being required in each case to move the same weight and kind of train. Wider gauge, however, permits the design of larger locomotives, much beyond the limit of capacity of the narrow-gauge, and the wider firebox and freedom from the cramped space of the narrow-gauge is a decided advantage. It is a fact that standard-gauge locomotives are worked on short stretches, such as approaches to coaling stations, etc., by adhesion, on grades as steep as 10%, and Shay geared locomotives regularly on grades of 4 and 5%; and, as noted previously, there are several lines of heavy traffic

worked by adhesion locomotives on grades between 3 and 4%, and until only recently the Canadian Pacific had grades of 4½% on its main transcontinental line worked by ordinary locomotives. The writer knows of no steeper grade than this regularly worked by adhesion on narrow-gauge.

As in the case of curves, steep gradients are not advocated as by any means desirable, but the ability to operate trains on them is not affected by gauge, except in the one very important item against the narrow-gauge of the very limited capacity of the locomotives as compared with the wider gauge. The heaviest locomotive of the Mallet type, built for narrow-gauge, weighs 176 tons, as compared with 425 tons for the heaviest standard-gauge, or in the proportion of 1 to 2.4.

Speed.—At present there is little demand in the Argentine for speeds in excess of those which can comfortably be maintained on narrow-gauge lines in first-class condition, but the growth of the country is so great that it is rapidly reaching the point where fast speeds will have to be maintained over long distances in order to get passengers and mail to their destinations within a reasonable time. There is no reason to think that the Argentine will long remain content with inferior service, but will expect and will get as good service as is obtained in North America, with which region its transportation system will be most closely comparable.

A tabulation of the regular schedule of the principal long-distance and fast trains in the Argentine at the present time shows the maximum and average speeds to be as follows:

	Kilometers per hour: Maximum.	Average.	Miles per hour: Maximum.	Average.
Broad gauge.....	61.8	46.3	38.4	28.8
Medium "	30.0	28.4	18.6	17.6
Narrow "	39.6	29.0	24.6	18.0

It is well known that in Europe speeds of 50 to 56 miles per hour are maintained regularly for distances of 200 miles and more by a large number of trains daily. There are many fast trains in the United States, at least 25 or more daily, which do as well or nearly so, though they are much heavier.

On the transcontinental and other long-distance runs in the United States, varying from 1 000 to 2 500 miles, average speeds of 35 to 40

miles per hour are maintained, and daily trains between New York and Chicago on two roads average more than 50 miles per hour for the 1 000-mile run.

Most of the lines in the Argentine, and practically all those cited, have very light gradients and good alignment, whereas, in the United States, most of the lines, especially the transcontinental lines where they cross the Rocky Mountains, have sections of long heavy gradients with considerable curvature; so that, both actually and comparatively, the Argentine is far behind the United States and Europe in the matter of speed, and the narrow-gauge lines are far behind the broad-gauge. The medium-gauge lines of the Entre Rios and the North East Argentine Railways can hardly be considered for comparison at present, as they are not in good physical condition, but they already have in hand plans looking toward an improved service between Buenos Aires and the North which should enable them to run their trains through to Posadas or Corrientes in about 24 hours, or at an average speed of 30 miles per hour, or faster if necessary.

In a discussion before the Institution of Civil Engineers of Great Britain in regard to the gauge of Indian Railways, and in reply to a question as to whether high speed was necessary in that country, the statement was made that, "India, like every other country, had progressive ideas of speed, comfort, and safety, and these would have to be met." There can be no question, also, that this applies equally to the Argentine and Brazil.

For passenger service the narrow-gauge is hopelessly handicapped, and can never meet the requirements of modern railway service either in speed, comfort, or safety. An ordinary through passenger train in the Argentine will consist of about twelve coaches, part of which will be sleepers, diners, etc. Such a train in the United States would weigh between 700 and 800 tons loaded, but, owing to the generally lighter construction of the Argentine rolling stock, the total weight on the broad- or medium-gauge lines there would be about 500 tons, and on the narrow-gauge, with the same type of rolling stock, it would weigh about 400 tons, with less than three-quarters the capacity.

It is possible, on narrow-gauge lines, in first-class condition, with the best design of engine, to reach a maximum speed of 50 miles per hour on a level grade with a comparatively light train (250 to 300 tons).

On grades even as light as 0.5 to 0.6%, which are the ruling ones on most of the lines of heavy traffic of the Argentine, and are the grades on the Central Cordoba Railway line between Buenos Aires and Rosario, the best average speed would hardly be more than 40 miles per hour, which would mean that the Central Cordoba could not, at the best, make the journey in less than 4½ hours, as compared with the present actual time of the Central Argentine Railway of 5 hours, and the possibility of the latter doing it easily in 3½ hours, if necessary, that is, at an average speed of about 50 miles per hour for the run.

With a train of 400 tons, the sustained speed between stations on the narrow-gauge, with very good track, will not exceed 40 miles per hour, and the average speed of express trains, including stops not oftener than, say, once every 62 miles (100 km.) will not be more than 35 miles. This speed might be adequate, but it can only be attained on almost perfect track, and even then at a considerable sacrifice of the margin between safety and recklessness. The effect of every slight irregularity in the track is felt very much more on the narrow-gauge than on medium or broad, and in this respect the broad has an advantage over the medium in a country like the Argentine, where stone or gravel ballast is so expensive.

Stability.—The lesser stability of the narrow-gauge will be immediately realized when one stops to consider that the height of passenger coaches must be practically the same, no matter what the gauge is. Considering the gauge reduced to a minimum with the height remaining the same, it can be seen that a difference in level of the two rails of, say, ¼-in.—less than that of many low joints in earth ballast—would be sufficient to overturn a sufficiently narrow and high vehicle, whereas it would have very little effect on a wide one, even at high speed. Then again, as soon as unevenness develops in the track, the shock caused by passing trains is greater on the narrow-gauge by reason of the high center of gravity, more height in proportion to width, and becomes worse much more quickly, thus increasing the cost of maintenance and making the hard-riding track so often noticed on narrow-gauge roads. Fig. 1 will, perhaps, help to emphasize this point, which is quite important and often lost sight of by those who compare the efficiency of rolling stock on one gauge or the other.

The growing realization of the fact that the speed and weight of modern trains are producing stresses, even in the very best of modern track, far greater than were formerly suspected, is shown by the action of the Canadian Society of Civil Engineers, which, recognizing the probable existence, due to increased loads, of stresses not satisfactorily distributed by the old short ties, has advocated a longer tie.

The Railroad Commissions of the States of Pennsylvania and New York have ordered a reduction in the speed of the fast 18-hour Chicago trains, due to the difficulty of keeping the track in sufficiently good condition to permit these high speeds. The following is from a recent editorial in a technical journal:*

"It seems to us worth while at this time to enter strong protest against any further increase in the loads which are imposed on the steel rails, track and bridges of American Railways."

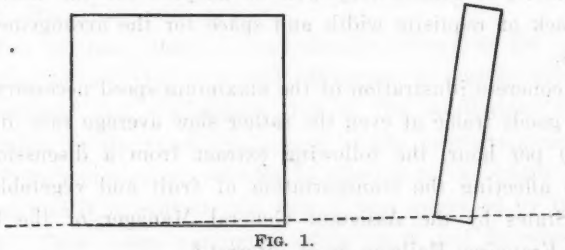

FIG. 1.

In the same journal† there is the following:

"The problem of weight is particularly difficult in regard to passenger locomotives [United States 4 ft. 8½ in.-gauge] * * *. Already we have axle loads of 60 000 to 68 000 lb., and the impact effect or 'hammer-blow' of such loads at high speeds is very severe upon joints, frogs, low spots, and the track in general."

The foregoing comments receive additional force when applied to narrow-gauge roads, where the much greater height in proportion to the width of the vehicles imposes additional shocks and much greater impact stresses than on the wider gauge.

It is well known, of course, that in the transmission of the power from the reciprocating parts of the locomotive engine to the wheels there is an unbalancing of forces which is only partly overcome by the counterbalancing of the wheels. Take, for instance, a Pacific type

* *Engineering News*, December 26th, 1912.
† July 11th, 1912.

engine with 60 000 lb. per axle, running at 60 miles per hour, the rail pressures under each wheel will vary from about 20 000 to 40 000 lb. at each revolution, according to the position of the counterbalance in relation to the rail.

An attempt to overcome this has been made in the class of engines known as balanced compounds, which have been used to a somewhat greater extent in Europe than in the United States. In this type of counterbalanced locomotive the four cylinders are arranged in a row, two inside and two outside the frame, and by the alternating action of the units of each pair they tend to overcome much of the unbalancing of forces noted above. It is hoped that the use of this type will tend to reduce the excessive track stresses with which we now have to contend, but, on account of the necessary arrangement of the cylinders, it cannot very well be adopted for the narrow-gauge, due to lack of requisite width and space for the arrangement of the cylinders.

As a concrete illustration of the maximum speed necessary in order to move goods traffic at even the rather slow average rate of 15 miles (24 km.) per hour, the following extract from a discussion of the problems affecting the transportation of fruit and vegetables in the United States by the Assistant General Manager of the St. Louis and San Francisco Railway, is of interest.*

Citing the run from New Orleans to Denver, 1 515 miles (2 438 km.), he states that at an average speed of 15 miles per hour, which seems quite slow for fruits and vegetables, the total time on this trip would be 101 hours. To get the actual running time there would have to be deducted:

Time lost at 10 district terminals, 1½ hours each	= 15 hours.
Time lost on each of 10 divisions of a single-track road for passing other trains, taking water and coal, say, 2 hours each	= 20 "
Total	35 hours.

This leaves 66 hours actual running time, or an average speed of about 24 miles (39 km.) per hour. In order to make this average speed, and considering the time lost for slow speeds on heavy grades,

* *Railway Age Gazette*, February 7th, 1913.

slowing down for orders (this particularly in the Argentine with the "Via Libre" system), signals, crossings, junctions, etc., makes it necessary to attain a speed of 40 miles (65 km.) per hour at least, on a good proportion of the distance.

To do that with the average freight train necessitates quite good track—it certainly would be verging on the dangerous to attempt it on even fairly good track on the narrow-gauge.

Rolling Stock.

One of the claims in favor of the narrow-gauge most frequently heard is that of the better utilization of the rolling stock; that the width of the cars is greater in proportion to the width of the gauge than it is on the wider gauges; that there is less dead load to paying load, and often that it is cheaper.

The first of these claims is undoubtedly correct, as far as it goes, but whether or not this is a real advantage is questionable, for, as already pointed out, the impact due to the oscillations caused by imperfections in the track (by reason of the proportionately greater height of the meter-gauge vehicles in relation to the width of gauge) is greater, and it is evident that this is also increased by the greater overhang. This causes a rougher-riding track and increased cost of maintenance, the narrow-gauge being forced to the limit in the matter of overhang, in order to provide reasonable capacity. That the other claims cannot be substantiated is believed to be shown by the following discussion.

Passenger Cars.—When it is considered that for passenger trains the capacity of the narrow-gauge is only three passengers in the same length of coach as will provide accommodation for four on either the medium or broad, it is seen at once that the slight extra cost of construction of the latter is more than justified. Comparing the medium and broad, the medium accommodates four passengers quite comfortably, two on each side of the aisle, the broad-gauge does the same, with some slight excess of room, and it is useless for passenger business to consider increasing the width of the broad-gauge, because, to be effective, this would involve three passengers on one side and two on the other, which, besides making unequal loading, would not be comportable and, therefore, is out of the question. In the dining

cars the medium gauge in the Argentine only allows for three passengers in the width of the car, though four can be accommodated by the broad, and this is the only place where the latter takes any advantage of its increased width. The latest type of all-steel diners in the United States, however, accommodates four passengers, two on each side of the aisle. In sleeping cars, whether of the Pullman type, or with compartments with transverse berths, as in general use in the Argentine, the medium-gauge is quite equal to the broad, and has generally less dead weight per passenger. When divided into compartments, the medium is wide enough to provide comfortable berths crossways of the car, and this is all the broad-gauge can do. If the Pullman type of car is used, the broad-gauge only gives more space in the aisle, which is of no advantage, so that the medium is at a slight advantage over the broad in the sleeping cars. On the narrow-gauge, compartments with berths across the cars are really impractical, although some have been built this way and the space quite ingeniously utilized, yet the berths are not long enough to be comfortable for the ordinary man. The narrow-gauge, therefore, is practically forced to the Pullman type of berths, placed lengthwise of the car, but utilizing only one side of it (as compartments have to be provided) so that they only have about one-half the capacity per unit of length of train that the medium-gauge has, and the dead load per passenger in narrow-gauge sleepers is about 2 tons, as compared with 1½ tons on medium or broad.

In order to determine, as far as possible, the relative capacity, cost, etc., of rolling stock on the different gauges in the Argentine, such information as could be obtained was collected, and is presented herewith for what it is worth. It is not as complete as might be wished, and, of course, comparison of rolling stock in any way is only valuable if the type of construction is the same. Practically, it is obvious, however, that given the same type of construction, the spacing of the wheels can make little if any difference, and these actual figures are given simply as confirmation to show that there is little difference in actual practice. The details of the passenger equipment are given in Table 3.

It will be noted that, in regard to cost, although the difference between the cost per ton as between narrow and medium is about 19%.

the difference in cost per passenger accommodated is 34%, both in favor of the medium-gauge.

Freight Cars.—The advocates of the narrow-gauge, though generally admitting that for passenger business the broader gauges have some advantage, almost invariably claim an equality in transportation of freight, within the limits of their capacity, and that their rolling stock is cheaper and has less dead weight in proportion to carrying capacity.

Cost per passenger.....	361	238	264
Weight per passenger, in tons..	0.82	0.67	0.75

It is generally claimed that in the Argentine there is not much demand at present for either very long trains or cars of large capacity. Leaving this phase of the question for the present, it will be of interest to compare the freight cars of the three different gauges on somewhat the same basis as the passenger cars.

In regard to certain types, some additional data have been furnished to the writer by the Middletown Car Company, which has supplied a large number of narrow-gauge cars to the Government lines, and also to a standard-gauge line in Uruguay and to the broad-gauge port railway at Buenos Aires, these cars being of the same general types of construction. It is to be noted that the comparison of freight cars is somewhat difficult by reason of the greater variation in types of construction, the proportion of tare to total capacity

varying from 40% for well-designed cars to as much as 60% in some of the older types of less capacity. In the United States, also, the cars of large capacity show up to much better advantage than those of smaller capacity, as the underframes and draft rigging have to be the same for all, in order to allow all types of cars to be used in heavy trains. As far as possible, however, from the data of a large number of cars examined, the following are selected as representing good average practice in the Argentine for well-designed cars of fairly large capacity.

The question of what the result would be if the broad-gauge cars were changed so as to get the same proportionate overhang as medium-gauge, is discussed later, and the following comparisons are made on the basis of existing conditions, which it is unlikely will be changed.

It is to be noted that the greatest variation is to be found in the cost of the cars of the Rosario Puerto Belgrano Railway, which is considerably above the average. It is believed that, if sufficient information could be obtained as to the cost of freight cars on the other principal broad-gauge roads of the country, it would show little variation from the costs given of narrow and medium-gauge. The tons are metric, of 1 000 kg. (2 205 lb.).

TABLE 4.—Data Relative to Covered Wagons (Box Cars).

	Capacity, in tons.	Area of cross-section, in square feet.	Cubic feet.	Tare, in kilogrammes.	Cost.
Narrow.					
Middletown Car Company	30	51	1 695	12 200	.....
Central Cordoba	25	45	1 340	10 500	$1 386
Central Northern	20	.....	.....	10 000	1 100
Medium.					
Middletown Car Company	30	70.7	2 545	15 380	.....
Entre Rios	30	73.4	2 350	12 500	$1 470
Broad.					
Middletown Car Company	30	71.1	1 860	12 675	$1 400
Rosario Puerto Belgrano	40	75.1	2 885	.....	2 075
Southern	40	.....	2 220	15 120	1 875
Central Argentine	40	.....	2 185	16 350	1 875

It will be seen at once that, as far as regards weight of car to capacity in tons, there is little difference, with the exception of the Middletown Car Company's medium-gauge car, which has very large cubic capacity, the 30-ton cars averaging about 40 to 42 per cent. These small differences are less than are to be found between cars on any one line, of different types of construction.

It will be noted, however, that the narrow-gauge cars have generally only about two-thirds the cubic capacity of the wider gauges. The Middletown Car Company's broad-gauge car is quite a short one, being only 26 ft. long (the usual length being 36 ft., more or less), and, as a large proportion of the goods hauled in box cars is bulky rather than heavy, the extra cubic capacity is a most decided advantage. In the Argentine, as nearly as can be calculated from the statistics published by the Government, more than one-half the freight generally handled in box cars is of the former class, that is, classified by bulk rather than weight.

TABLE 5.—Data Relating to Stock or Cattle Cars.

	Capacity, in tons.	No. of animals.	Width, inside.	Floor area, in square feet.	Tare, in kilogrammes.	Cost.
Narrow.						
Middletown Car Company	30	.....	7 ft. 11 in.	231	11 984	.....
Central Northern	20	16	.....	190	10 768	$1 240
Central Cordoba	22	20	8 ft. 0 in.	232	12 000	1 365
Medium.						
Middletown Car Company	26	.....	8 ft. 5 in.	295	15 380	.....
Entre Rios	22	20	7 ft. 10 in.	256	12 000	$1 475
Broad.						
Rosario Puerto Belgrano	40	24	7 ft. 3 in.	281	.....	.....
Pacific	28	.....	9 ft. 6 in.	323	16 000	.....
Pacific	28	.....	9 ft. 6 in.	314	17 525	.....
Average of several	40	.....	8 ft. 6 in.	295	16 250	.....

Stock cars are comparable on the basis of the relation between the floor area and the tare weight. The data in Table 5 are all the specific examples the writer has been able to get, and, in spite of being taken

from various sources, they show considerable agreement, the relation between floor area and tare weight for the three types being as follows:

Narrow	51.9	kg.	per	sq.	ft.	(114 lb.)
Medium	49.7	"	"	"	"	(109 ")
Broad	46.9	"	"	"	"	(103 ")

It may be noted that the Entre Rios car is very small for a stock car for 4 ft. 8½-in. gauge, and is not at all representative of the best practice, which would be at least equal to the others. The prices per ton of car and per square foot of floor area work out as follows:

Narrow: Central Northern	$115.15	per ton	$6.75	per sq. ft.
" Central Cordoba	113.75	" "	6.40	" " "
Medium: Entre Rios	118.75	" "	5.75	" " "
Broad: Rosario Puerto Belgrano	.....	.....	.....	.....

TABLE 6.—DATA RELATING TO GONDOLAS.

	Capacity, in tons.	Floor area, in square feet.	Cubic feet.	Tare, in kilogrammes.	Cost.	
NARROW.						
Middletown Car Company	30	250	804	10 900	.....	.....
Central Cordoba	25	244	.....	11 000	$1 000	.....
Middletown Car Company	30	250	.....	12 210	1 345	All steel.
Middletown Car Company	20	.....	.....	9 070	840	.....
MEDIUM.						
Middletown Car Company	30	292	.....	12 845	.....	.....
Entre Rios	30	284	.....	11 250	$1 250	.....
Rosario Puerto Belgrano	37	308	700	14 400	.....	.....
BROAD.						
Middletown Car Company	45	.....	.....	13 800	.....	.....
Central Argentine	42	336	788	15 240	.....	.....
Western	45	340	1 630	15 200	.....	.....

For gondolas the comparison is best made between floor areas and tare weights. The cubic capacity is affected by the height of the sides, and as these may vary quite a little, this is not made, as all the details

are not available, also the loads in these cars are often heaped up above the sides.

Narrow ..... 45.8 kg. per sq. ft. of floor area (101 lb.)
Medium ..... 43.5 " " " " " " " (96 ")
Broad ..... 47.5 " " " " " " " (105 ")

TABLE 7.—DATA RELATING TO FLAT CARS.

	Capacity, in tons.	Floor area, in square feet.	Tare, in kilogrammes.	Cost.	
NARROW.

Average of seven cars	41	328	13 706	.....	.....

Narrow ..... 34.0 kg. per sq. ft. of floor area (75 lb.)
Medium ..... 40.0 " " " " " " " (88 ")
Broad ..... 41.7 " " " " " " " (92 ")

It will be noted that, in comparing these four types of freight cars, so far as these figures show, there is very little difference between those of either gauge, what difference there is, however, being in favor of the wider gauges, especially for the box and cattle cars. The data are not as complete as might be wished, but are all that are available of Argentine rolling stock at this time, and, in view of the fact that the information has been taken just as it came, it is believed that it confirms what must be seen to be theoretically correct, that is, that gauge can make very little difference in cars of small capacity. A narrow-gauge box car with the wheels spread out can be used perfectly well on broad-gauge tracks which only differ from its own in being slightly wider. This extra width of trucks, as between narrow and

medium, only involves about 200 to 250 lb. more iron and steel, which at 6 cents per lb. is from $12 to $15, and this extra width is more than compensated by the increased stability and, consequently, lesser impact on the track.

The claim, therefore, that narrow-gauge cars are either cheaper or lighter in weight than cars of the same capacity and same type of construction for wider gauges, does not appear to be sustained by the facts, such variations as are shown being less than those between many cars of different make and design on the same railroad. It is of little value to include for comparison data relating to ordinary United States rolling stock, as this is all generally of heavy type, all the underframes and draft rigging being much heavier than those in use elsewhere, in order that they may withstand the strains due to the use of the cars in heavy trains, and, in addition, all cars are equipped with automatic power brakes, which are not in general use in the Argentine. The railways of the latter country, however, are beginning to realize the values of the saving due to the use of heavier cars and trains, and perhaps more so on the narrow-gauge lines. They are handicapped, however, by the fact that the underframes and draft rigging of all their old rolling stock, and even much of the new, are too weak to stand the strain. They are just beginning to be forced into the same position as the railroads of the United States were some time ago, that is, to adopt the same heavy type of underframe and draft rigging, no matter what the size of the car is, in order to be able to transmit the tractive forces without danger of breaking the train. When this becomes general practice, there will be a much greater discrepancy in the relations between the gross and paying loads for the lighter cars, and they will show up at a much greater disadvantage than they do even now.

Cost of Locomotives.—It is practically impossible to determine with mathematical accuracy the relative economy of locomotives for one gauge or another, as they vary so much in detail. Even supposing three machines as exactly alike as possible, except for the difference in the width apart of the wheels, which would give a difference in cost of only a trifling extra quantity of steel for the wider spacing, the performance would be so different as to vitiate any comparison. Even supposing three machines designed to be as nearly alike as possible

but adapted to the gauge, there would still be so many differences that comparison would be questioned.

It seems to be a perfectly safe assertion, however, that, within the limits of the narrow-gauge, any reputable locomotive builder will undertake to build locomotives of each gauge having about the same power, capacity, and relative fuel economy for about the same price, irrespective of the gauge. There may be a little less steel in the narrow-gauge, but the labor for this slight difference is little, if any, less, and the greater ease of design for the broad-gauge more than compensates for this. There seems to be a vague idea in the minds of some advocates of the narrow-gauge that, by some means or other, narrow-gauge locomotives are more economical, whereas it is probable that the contrary is the case, as is noted in detail later. The hauling capacity of a locomotive, provided of course it is properly designed for power, is determined by the weight on the driving wheels, and a locomotive with 10 tons weight on its driving wheels will have exactly the same adhesion on a wide-gauge that it has on a narrow-gauge, so that, to pull the same gross load, the engines must have the same weight, if they are built on the same plan. A pound of coal, too, will not generate any more steam on the narrow-gauge than on the wide.

In order to get some idea at least of the comparative cost of locomotives for the three gauges in the Argentine, the writer obtained the figures given in Table 8, which, considering the different types of engines involved, different makers, etc., show a sufficient agreement in cost per ton at least not to disprove the argument that gauge makes little, if any, difference. The weights are per ton of engine and tender, light.

Size of Locomotives.—As at present worked, the 5 ft. 6-in. gauge has about the same capacity as the medium, though much heavier engines and trains are operated in the United States on the medium-gauge than elsewhere on any gauge. For reasons to be given later, it is believed that the capacity of the broad-gauge, measured by the size of engines and length of trains, will not be increased beyond that of the medium, unless by some entire change in transportation methods not even guessed at now.

The comparisons in Table 9, therefore, between the largest engines built to date (January, 1913), of the three types most generally in

use, will give a good idea of the tremendous advantage of the wider gauge in this respect for lines of heavy traffic.

TABLE 8.—DATA RELATIVE TO LOCOMOTIVES.

In the comparisons in Table 9 the 3 ft. 6-in. engines are given for the Pacific and Mallet types as they are the largest narrow-gauge engines, the largest meter-gauge engines of these types thus far built, however, are quite a little smaller, the meter-gauge Pacific type being 19 by 26 in., with a total weight of engine and tender of 229 500 lb. and the Mallet 18½ by 29 by 22 in., with a total weight of 323 500 lb.

The freight engines of both types on the medium-gauge have practically double the capacity, and though the superiority of the passenger engine in tractive power is not so great, the grate area is just double, 70 sq. ft. as compared with 35 sq. ft., and the total heating surface, 3 936 sq. ft. as compared with 1 981 sq. ft., so that the capacity for sustained work, so necessary in passenger service, is very much greater in proportion. Size of boilers, heating surface, and grate areas are the limiting factors, of course, in all types of locomotives, and though the limit seems to have been nearly reached in these items in locomotives for narrow-gauge, it does not seem to be in those for medium-gauge. It

	Goods.	3.3 to 1
On actual number of passengers carried 1 mile		2.0 to 1
On actual number of tons carried 1 mile		4.7 to 1

Engines on broad-gauge, average 7 838 000 ton-miles per annum.
Engines on narrow-gauge, average 3 962 000 ton-miles per annum.

The following extract gives the opinion of an important official of the inferiority of the narrow-gauge lines in India, where the problem is very much the same as it is in the Argentine, namely, the movement of very large quantities of grain in a short space of time.

"It has been clearly brought out, writes Major-General Kennedy, by the facts of the present season's famine traffic, that occasions such as the present may arise when, in order to feed a large population, grain has to be carried over single lines of railway for long distances, in quantity sufficient to strain to the utmost the resources of the best appointed lines of the standard 5½-ft. gauge and, as it may be assumed that narrow gauge lines would be far less efficient, the unsuitability of the metre gauge for long lines of through communication cannot be put out of sight when thought is taken for the proper and efficient administration of a country liable to be affected with drought and famine.

* "The Railway Gauges of India," *Minutes of Proceedings*, Inst. C. E., Vol. CLXIV, p. 202.

"Although the railway lines concerned in the present case, *i. e.*, the East Indian, the Great Indian Peninsula and the Madras Railways, have failed to do all that was required of them, or that was needful to meet the full necessities of the case, they have, nevertheless, it may be truly said, largely contributed to save Southern India from a very great calamity, but they have not done this with any margin to spare, or without some injury to particular sections of general trade or to individual traders. The standard gauge lines have been barely able to satisfy essential and urgent demands, and under similar circumstances narrow gauge lines would probably have broken down altogether. Indeed, it is known that in the Southern part of the Madras Presidency considerable inconvenience arose at a break of gauge.

"We may, with the memorial of the Bombay Chamber of Commerce before us, take it as proved that narrow gauge lines are unable to meet the sudden demands likely to be made upon them in India, and that they are far more expensive to work than broad gauge lines. At first sight it is difficult to see how the latter statement can be true, but we think we can clear up the point in a moment. When a given quantity of goods, say grain, has to be conveyed over a railway, two systems of conveyance may be adopted, that is to say, we may run large trains at long intervals or small trains more frequently. Now, on the broad gauge lines in India a goods train complete weighs on the average 505 tons, but on the Rajpootana State metre gauge railway the average goods train weighs but 200 tons, so that the broad gauge trains are really 2½ times as heavy as the narrow gauge trains, while their speed is higher."

Economy of Heavy Engines.—The following statement, recently made by J. J. Hill, F. Am. Soc. C. E.,* one of the foremost railroad executives in the United States, shows the value and importance of heavy engines and wagons of large capacity for the development of cheap and efficient transportation:

"Heavier rails, larger engines, cars of greater capacity, increased train movement and the full utilization of equipment have kept business moving. The density of traffic in England, France and Germany should be as much greater than in the United States as the density in the middle exceeds that in the far western states. Yet here are the facts:

"Ton Miles per Mile of Road.	
France	496 939
United Kingdom	529 622
Germany	827 400
United States (1910)	1 071 096

* *Railway Age Gazette*, December 20th. 1912.

"* * * Our railroads move 272 ton miles of freight per dollar of net revenue, where the United Kingdom shows only 58, Germany 172 and France 88.

* * * * * * * * *

"Transportation costs the public from one-third to one-half as much here as in Europe. This cheapness is not purchased at the cost of the workingman. In 1910 the average daily earnings of railway employees in the United States were more than twice as great as in the United Kingdom, and two and three-quarter times as much as on the Prussian-Hesse system in Germany."

There has been some criticism of the exact figures used by Mr. Hill, and of the use of certain units as indices of efficiency, but, making every allowance for this and the fact that such criticisms of details are always possible, in view of the different conditions and manner of computing and compiling statistics, there is not enough difference to affect the main argument, which is, that the use of heavy rolling stock has been the principal cause of the very much lower costs of transportation in the United States than elsewhere.

Fig. 2,* relating to the improvement in operating efficiency of the Chicago, Burlington and Quincy Railroad during the past 10 years, shows with great clearness the possibilities of reduction in operating expenses by the increase of train loads. During this period, as shown by the diagram, the business of the road was nearly doubled (98.3% increase), though there was at the same time an actual decrease of 9.8% in the number of trains required to handle it. Part of this good showing was made by increasing the car loading, that is, the revenue-tons per car-mile, by 45.5% and the remainder was due to increase in the capacity of the locomotives, reduction of grades, and the maintenance of the roadbed and equipment in a high state of efficiency. The average capacity of cars was increased from 23 to 38 tons. The heaviest type of locomotive in use in 1901 developed about 20 000 lb. tractive power; the Mikado (2-8-2) type now in general use has a tractive power of 60 000 lb. The average train load is now 438 revenue-tons per train-mile, as compared with 200 tons in 1901.

Although Canada is somewhat behind the United States in the matter of economical handling of freight, it is far ahead of any other country in this respect. In New South Wales, where they are vig-

* *Railway Age Gazette*, January 18th, 1913.

orously agitating the double-tracking of many of their lines, the traffic density is only 226 906 ton-miles per mile as compared with 731 776 for Canada, the average train loads being 90 tons and 325 tons, respectively, so that actually more trains are being run in New South Wales to handle a smaller volume of traffic than in Canada, the freight-train-miles per mile of line in New South Wales being 2 512 as compared with 2 252 in Canada, in spite of the fact that the density on the latter is 220% more than on the former, and the average freight charge in Canada is 0.75 cent as compared with 1.78 cents in New South Wales.

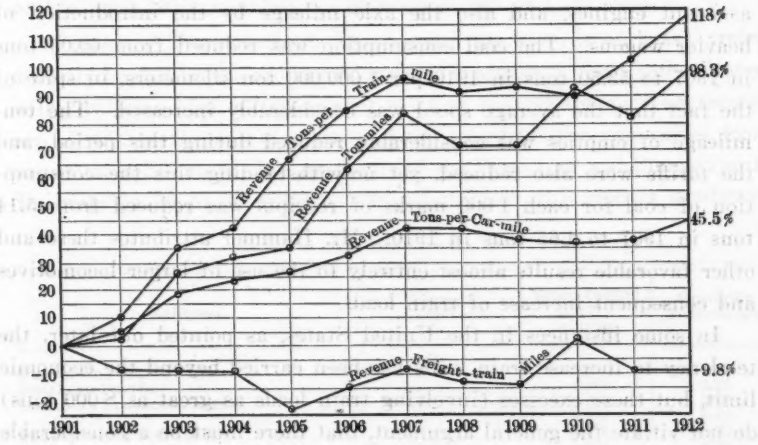

FIG. 2.

It is not only in the United States and Canada, however, that the introduction of heavier locomotives, and consequent increase in train loads, has been found profitable and economical. About 10 years ago, as the result of investigation into the so-called "American" methods of operation, Sir George Gibb, then Manager of the North Eastern Railway of England, introduced changes on that line which have resulted in the increase of the average freight train load from 60 to 95 tons, and on mineral trains from 114 to 184 tons. The result of this* is seen in the fact that for the last half of 1912 a dividend was announced at the rate of 7½% per annum, more than twice the average for British railways.

* *Railway Age Gazette*, March 28th, 1913.

In Germany, also, according to a statement of Mr. Hammer,* there is a growing realization of the necessity for the use of larger locomotives. On the Prussian State Railways (as elsewhere), owing to the continued tendency to increase the dead weight of passenger equipment, both actually and per passenger, in order to provide the better accommodations demanded by the traveling public and also the greater strength required for increasingly high speeds, the average weight per seat on passenger equipment has increased from 0.27 to 0.37 tons, or 37%, in the last 20 years. The introduction of heavier locomotives has reduced the train and locomotive mileage by eliminating many assistant engines, and also the axle mileage by the introduction of heavier wagons. The coal consumption was reduced from 60.05 tons in 1907 to 53.50 tons in 1910 per 1 000 000 ton-kilometers, in spite of the fact that the average speed was considerably increased. The ton-mileage of empties was considerably reduced during this period, and the tariffs were also reduced, yet notwithstanding this the consumption of coal for each 1 000 marks of receipts was reduced from 5.14 tons in 1907 to 4.65 tons in 1910. Mr. Hammer attributes these and other favorable results almost entirely to the use of larger locomotives and consequent increase of train loads.

In some instances in the United States, as pointed out later, the tendency to increase train loads has been carried beyond the economic limit, but these excesses (involving train loads as great as 8 000 tons) do not vitiate the general argument, that there must be a considerable increase in the Argentine to meet the necessities of modern transportation and to carry bulk freight long distances at rates which will enable the hitherto undeveloped sections in the interior of South America to enter the markets of the world, and that the necessary increase is not possible on the narrow-gauge.

Saving in Fuel.—The saving in coal consumption, made possible by the use of some of the more recent types of heavy engines, is also shown by the following quotation from a recent paper† by Mr. O. S. Beyer, Jr. In commenting on fuel, he said:

"Numerous tests and service records have revealed that large superheater Mikado locomotives which have been placed in service recently haul trains of 45 and 50% greater tonnage with the same amount of

* *Bulletin*, International Railway Congress, March, 1913.
† Am. Inst. of Mech. Engrs., Vol. 34, 1912, p. 1301.

coal that was formerly consumed by the Consolidation locomotives they replaced. Even the coal consumption of Mallet engines with grate areas up to 100 sq. ft. has not grown in any way proportionate to the increase in their hauling capacity. Modern engines when running at shortened cut-offs over those portions of the road other than the ruling grades exhibited a still greater economy than when working on the heaviest grades. Some service tests of recently built Mikado engines on the Delaware, Lackawanna and Western Railroad clearly demonstrated these facts. Their economy in fuel consumption as compared with that of the old Consolidation type, both operating over heavy grades at full load, being 20 per cent. The economy effected over easy grades while running at shortened cut-offs was 39.3 per cent. almost twice as much. The average was 29.1 per cent."

Weight of Trains.—Table 11, showing the records of heavy trains actually hauled in the ordinary course of business in the United States, will give some idea of the present state of the art there. The records are all within the past 3 years, and the length of the run varies from about 125 miles on the low gradients of the Virginian and Pennsylvania Railways to 50 to 65 miles on the other lines with steeper gradients.

TABLE 11.

The last five trains carry coal or iron ore in all-steel gondolas, all of the same type and of 100 000 lb. capacity, having 85 to 100 cars in a train.

Wider Rolling Stock for Broad-Gauge.—This brings us to the consideration of possible benefits to be derived from the broad-gauge, if advantage should be taken of the extra width of track to get the same proportionate width of cars as the medium- or narrow-gauge.

Experience has shown that the width now in use on the meter-gauge, combined with the height of passenger coaches, box cars, and cattle cars, is practically at or even beyond the limit. One has only to travel

on meter-gauge lines, even where the track is well kept up, to realize that as soon as any attempt at speed is made the oscillations are quite violent, and if the track is out of line and surface, speed becomes positively dangerous.

On the standard-gauge, which is well named the normal in many countries, the happy medium appears to have been most nearly attained by proper adjustment of the size of the vehicles to the width of the track. The clearance diagrams, Fig. 3, which are those established for the Argentine, show the ratios in Table 12 between the clearances on the three gauges; and it may be noted that the clearances for medium-gauge are ample for the largest equipment in use in the United States.

TABLE 12.

Gauge.	Permissible width. Argentine.	Width of track.	Ratio.
Broad	11 ft. 1¾ in.	5 ft. 6 in.	2.0 to 1
Medium	10 ft. 10 in.	4 ft. 8½ in.	2.3 to 1
Narrow	10 ft. 6 in.	3 ft. 3⅜ in.	3.2 to 1

TABLE 13.—RATIOS BETWEEN THE ACTUAL WIDTHS OF VEHICLES AND WIDTHS OF TRACK.

Gauge.	Actual width of vehicle.	Width of track.	Ratio.
Broad	10 ft. 6 in.	5 ft. 6 in.	1.91 to 1
Medium	10 ft. 2 in.	4 ft. 8½ in.	2.16 to 1 (Freight cars only 9 ft. 4 in.)
Narrow	9 ft. 1 in.	3 ft. 3⅜ in.	2.77 to 1

The statement is often made—and at first sight apparently with a certain amount of reason—that the broad-gauge has not taken proper advantage of the additional width of gauge. It has already been shown that there would be no advantage in increasing the width of passenger coaches. Up to the present there has been little demand for freight cars of greater capacity than 100 000 lb. (45 000 kg.), but, if there were, it could be met, up to at least 20 to 30% more, without increasing the width of any type. The only possible advantage of the increased width would be that, theoretically, a reduction in cost would be possible, because the nearer the body of the car approches a square in plan the more economical it is to build, and in this the 5 ft. 6-in. gauge has a

superiority over the meter-gauge which more than compensates for the cost of the additional width of track. Between the present width of the broad-gauge rolling stock (10 ft. 6 in.), however, and the width to make it proportionately equal to the medium-gauge, say 12 ft., there

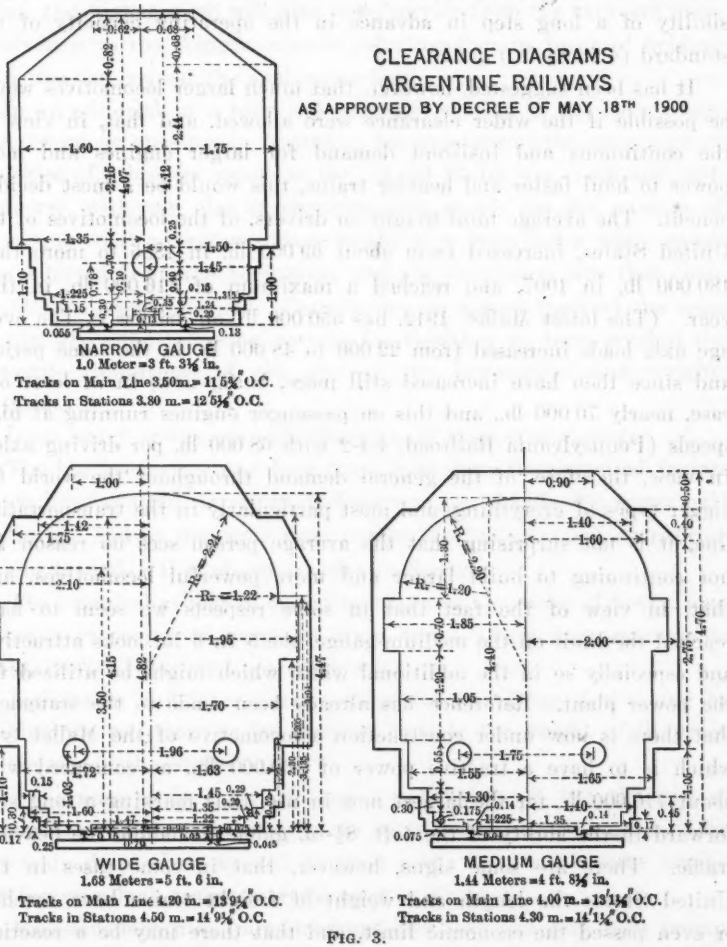

FIG. 3.

would be little saving in the cost of the vehicles, and no advantage in carrying capacity, even though the increased cost of additional clearance required for overhead structures, tunnels, etc., is practically negligible in the Argentine, as there are so few. There has recently been

designed for the Norfolk and Western Railway, and placed in service, high-sided steel gondolas of 100 tons capacity, weighing light about 65 000 lb., and having a simplified form of six-wheel truck. These cars are 10 ft. 4½ in. wide, over all, and their use indicates the possibility of a long step in advance in the operating capacity of the standard (4 ft. 8½ in.) gauge.

It has been suggested, however, that much larger locomotives would be possible if the wider clearance were allowed, and that, in view of the continuous and insistent demand for larger engines and more power to haul faster and heavier trains, this would be a most decided benefit. The average total weight on drivers, of the locomotives of the United States, increased from about 69 000 lb. in 1885 to more than 180 000 lb. in 1907, and reached a maximum of 316 000 lb. in that year. (The latest Mallet, 1912, has 550 000 lb. on drivers.) The average axle loads increased from 22 000 to 48 000 lb. in the same period, and since then have increased still more, being now, in at least one case, nearly 70 000 lb., and this on passenger engines running at high speeds (Pennsylvania Railroad, 4-4-2 with 68 000 lb. per driving axle). In view, therefore, of the general demand throughout the world for bigger types of everything, and most particularly in the transportation line, it is not surprising that the average person sees no reason for not continuing to build larger and more powerful locomotives, and that, in view of the fact that in some respects we seem to have reached the limit on the medium-gauge, the 5 ft. 6 in. looks attractive, and especially so in the additional width which might be utilized for the power plant. Reference has already been made to the statement that there is now under construction a locomotive of the Mallet type which is to have a tractive power of 160 000 lb., as compared with about 110 000 lb. for the largest now in use, thus marking a long step forward in the ability of the 4 ft. 8½-in. gauge to handle the heaviest traffic. There are some signs, however, that in some cases in the United States the length and weight of freight trains have reached or even passed the economic limit, and that there may be a reaction from the extremely heavy loadings, though by no means to reduce them to anything like the low standards of Europe or South America.

It has been pointed out* that these extremely large engines have

* *Engineering Record*, February 20th, 1909.

greatly increased the cost of bridges, and that heavy locomotives, because of the increased stresses in the track, increase the cost of maintenance. High speed, combined with heavy weights, is the cause of far more rail failures than poor steel. Lighter locomotives, shorter trains, and higher speed will give more service from the cars and more satisfaction to the shipper, who is not altogether in favor of holding trains for the last car the engine can haul.

In an editorial in a technical journal* relating to the controversy over the gauge question in Australia, the question of the advantage or otherwise of a broader gauge in the United States was examined; not, of course, with any idea of changing, but purely for the purpose of discussing what advantages there might have been had a wider gauge been adopted from the beginning, and the conclusion was that there would have been no benefit. Considering the matter further† the same journal gives the following reasons for thinking we have reached the economic limitations of the size of the locomotives and weights of trains:

Long heavy trains are only desirable if they save money.

The big locomotive and long train have been the principal factors which have enabled American Railways to pay double the wages paid in Europe and at the same time reduce the ton-mile cost of hauling freight far below that of any country in Europe.

The principal saving in operating expenses by reason of heavy, long trains is in saving in wages of train crews, which item amounts to about 12½% of the total operating cost.

Legislation and labor organizations are nullifying this saving by making the pay more or less proportionate to the weight of the train or the size of the engine.

An argument in favor of long trains has been that the cost of controlling a train is practically the same whether it be long or short, but train despatchers as well as train crews have much more trouble getting very long trains over the road in time.

Excessive length of trains may and does interfere with their prompt and efficient handling at terminals or passing sidings, causing delay to other trains.

---

* *Engineering News*, December 7th, 1911.

† *Engineering News*, July 18th, 1912.

Heavy locomotives and high speed increase cost of maintenance very rapidly as they pass the normal, 125 lb. rails of open-hearth steel, with special alloys, are already being considered to meet the demands of heavy traffic, and this expense is a charge against the heavy locomotive.

Probably the most important consideration of all, however, is the item of rolling stock repairs which has increased very rapidly with the increased weight of train and power of the locomotive. A hauling power of 25 tons and upward cannot be transmitted through a long freight train without exerting enormous stresses upon draft gear, couplers, car sills, floors, etc. It is not the mere push or pull of the locomotive, but the transmission of the power in a series of waves or shocks, especially on lines with broken profiles.

This matter of the proper design of rolling stock, and the strengthening of the underframes and draft rigging, is one which is receiving considerable attention, but, of course, the raising of the general standard of efficiency in a matter of this kind is very gradual, and in the meantime there is a temporary halt.

Enough has been said, however, to show that the 5 ft. 6-in. gauge offers no advantage in allowing the use of heavier cars or trains than are now in general use or in contemplation on the 4 ft. 8½-in., and the latter is capable of much further expansion along these lines, even beyond what are to-day considered to be the economic limits.

Train Resistance.—The term "train resistance" is used to denote the combination of forces which have to be overcome to produce the movement of the train, these forces being affected by the character of the road and vehicles and, therefore, to some extent, by the gauge.

Train resistance is of two kinds: that due to the internal resistance of the train, and that due to gradients and curvature. Numerous experiments have been made to determine the amount of the former, with varying results due to the complex nature of the problem, but one fact is firmly established, that the resistance per ton of train is much less for loaded cars than for empties, and less for heavier cars than for light ones. For a train of loaded 50-ton coal or mineral cars, all of the same type, the resistance, at ordinary freight-train speeds on straight, level track, is often as low as 3 lb. per ton, whereas trains of miscellaneous cars in the United States, including a fair proportion of cars as light as 30 tons and some empties, will have a resistance as

high as from 7 to 10 lb. per ton, 7 lb., however, being about the maximum with fairly good conditions. There is no doubt, therefore, that in this respect the narrow-gauge, with its much lesser average weight per axle, is at a disadvantage when compared with the broad-gauge, but just how much it is impossible to say.

The following table shows the effect of the capacity of cars on the loads which a consolidation engine (118 tons) can haul on a 0.5% grade at 20 miles per hour. The capacity includes weight of car and load, and the tonnage is based on the formula of the American Railway Engineering Association ($R = 2.22\ T + 121.6\ C$):

20-ton	cars	.....	1 570	tons.
30	"	"	1 775	"
40	"	"	1 910	"
50	"	"	2 010	"
60	"	"	2 090	"
72	"	"	2 160	"

The resistance due to grade is the force required to lift a certain weight a certain height; its computation is an exact mathematical proposition, and is not influenced in any way by gauge.

The resistance due to curvature is probably slightly less on narrow-gauge than on broad-gauge. It is of two kinds: one is the friction of the flanges of the wheel on the rails, which is probably in direct proportion to the force required to change the direction of a body tending to move in a straight line, this being a function of the speed and weight, and having nothing to do with the gauge; the other is the slipping of the treads of the wheels on the top of the rails, and this varies with the width of the gauge. That the latter is a comparatively unimportant factor is realized when one considers that, for example, on a curve of 400 ft. radius with a central angle of 90°, the difference in the length between the outer and inner rails for 4 ft. 8½-in. gauge is 7.39 ft. and for the meter-gauge, 5.15 ft. On a curve of 1 000 ft. radius with a central angle of 30°, which is about an average curve in the Argentine, the difference between the outer and inner rails would be:

Broad	.....	2.88 ft.
Medium	.....	2.47 "
Narrow	.....	1.72 "

When it is considered that about 90.4% of the alignment in the Argentine, including in this all the mountain lines, is on tangent, this additional resistance due to the narrower gauge is practically negligible. On a strictly mountain line, with very heavy and continuous curvature, this additional resistance might be considered perhaps to be equal, roughly, to the additional resistance of the smaller class of rolling stock, but, for the average line, it would be considerably less. On the other hand, locomotives for the narrow-gauge, of equal weight and power with those of wider gauge, must necessarily be longer, and, therefore, the resistance encountered by them in passing around curves would be somewhat greater than with the shorter engines for wider gauge.

Taken altogether, therefore, it seems quite safe to say that the resistance per ton of train on narrow-gauge lines is greater than on wider gauge, and the cost of operation is thereby increased, though it is hardly possible to calculate the amount.

Costs of Construction.

The reasons which are most generally advanced by the advocates of narrow-gauge for the supposed economy in first cost of construction are as follows:

1.—The use of sharper curvature is supposed to permit better adaptation of the line to the conformation of the ground.

2.—The cost of earthwork is supposed to be less:

a.—For reason No. 1.

b.—Because they are narrower.

3.—The cost of bridging is supposed to be less:

a.—Because they are to carry lighter loads.

b.—Because they are narrower, especially the masonry.

4.—The track and rolling stock are supposed to be lighter.

All these reasons are invalid except those directly affected by the width, that is to say, the width of earthwork and the length of ties; and, theoretically, it is questionable if even these are. If the bridges, track, and rolling stock are lighter, they are correspondingly less efficient, and, generally, in lesser proportion, as, for instance, a 30-lb. rail will only carry one-quarter the load that a 60-lb. rail will.

In nearly all the discussions, etc., in regard to gauge, comparisons of costs are made between two or more lines already built, or the average cost of all the broad-gauge lines of a country is compared with the average cost of all the narrow-gauge lines. Such comparisons, of course, are valueless for the determination of the effect of gauge on cost of construction. The broad-gauge lines usually are of a much heavier type of construction, have heavier rails, heavier rolling stock, and more of it, expensive terminals, etc., as they usually do more business. To give only one example of the many which have been found in looking over previous discussions, the following,* is a very fair example of the kind of argument used and information on which arguments have often been based. Speaking of Indian railways, the statement was made that broad-gauge costs 2½ times as much as meter-gauge. If the Government of India had pinned its faith to broad-gauge it would now (1906) have 7 000 miles less of railroad. The cost of line in India having been £11 775 per mile for broad-gauge, as against £4 700 per mile for meter-gauge.

In the discussion following, it was pointed out that the broad-gauge lines did more business, had heavier work, that is, greater quantities of earthwork, larger terminals, etc., and that to take only one item, that of bridging and tunnels alone, these had cost Rs. 10 792 ($3 500) per mile for the broad-gauge as against Rs. 2 149 ($700) for the meter-gauge, so that if the meter-gauge lines had been built in the same location as the existing broad-gauge and equipped to do the same business (if this were possible) they would have cost quite as much.

In connection with the further discussion of this paper, the following estimates were made of the difference in cost of building broad- and narrow-gauge lines in India:

Sir John Hawkshaw	£360	per mile	= $1 800
Sir John Fowler	633	" "	= 3 165
Sir George Bruce	200	" "	= 1 000
Sir Guilford Molesworth	425	" "	= 2 125
and in Victoria, Australia	261	" "	= 1 305
and South Australia	350	" "	= 1 750

It is to be noted that these differences are somewhat less than those shown in the estimates which follow, and are more nearly what they

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXIV.

might be if the calculations were made on a strictly theoretical basis, and including only the actual outlay for labor and material. In the estimates which follow (which are discussed in detail), not only has every reasonable allowance been made for any difference there is, but the same proportion is carried through the percentage of contingencies, interest during construction, etc., which tends to increase them, so that what difference they show is the maximum possible.

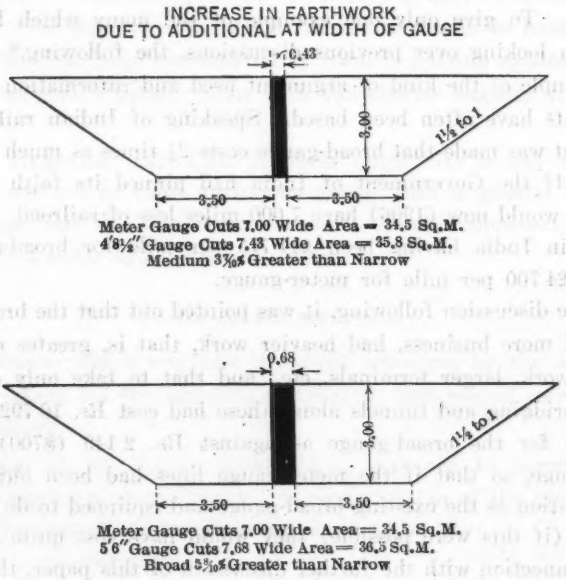

FIG. 4.

The only satisfactory method of determining the effect of gauge on cost of construction is to calculate what effect a difference of gauge would have, assuming the same conditions.

We have already seen that, within the limits of practical railroading for the gauges under consideration, curvature and gradients are not affected by gauge, therefore the location would be the same for lines of either gauge through the same country, for, in order to make a fair comparison, we must assume the road designed in either case to do the same business.

Taking each item of cost, therefore, we find:

Right of Way, Station Grounds, Terminals, etc.—These are not affected, the difference in width of earthwork being only 0.70 m. between meter- and broad-gauge, so that the width of right of way is not changed. If the tracks are spaced closer in terminals for narrow-gauge, they must be longer to hold the same tonnage.

Clearing and Grubbing.—There is no difference.

Earthwork.—This item is the one most affected by gauge, but the proportion is very small, as will be seen by the diagram, Fig. 4, showing, in the case of a cut or fill 3 m. deep, 4% more for medium over meter and 6% more for broad over meter. In making the calculations in the following tables, for lines with very heavy earthworks, an additional allowance has been made to cover the extra width in mountain work with steep transverse slopes, where the additional width involves somewhat more earthwork.

Bridging and Culverts.—The width of masonry is increased somewhat by reason of increased width of banks, but the amount is very small, about 2 to 4% for abutments, and from 0.2 to 1% for culverts, the end walls of the latter being the same, with only an increase of from 1 to 2 ft. in the length of the barrel. The steel work will be the same.

The latter assertion may be questioned, in view of the fact that much narrow-gauge rolling stock is lighter than medium or broad-gauge, but in order to avoid too much complication, it is assumed for purposes of this comparison that the same number of trains will handle the business, therefore the same weight of engine will be assumed. If any other assumption is made, that is, that heavier engines are used for the wider gauges, that means less trains and less cost of operation, which would compensate for the additional weight of the steel. The total cost of the actual bridging, omitting abutments, etc., is such a small proportion of the total cost of the railroad that any slight difference in this item would be very small.

Track.—Rails and fastenings will not be affected. The cost of rails is taken at $30 at Buenos Aires with about $150 per mile added for freight. The length of the cross-ties is affected directly as the width of the gauge, but as the function of the sleepers is to distribute the load, as well as to hold the rails in position, there would only be as many required for broad-gauge as would give the same bearing

area on the soil or ballast as those of the narrow-gauge, and, therefore, theoretically, there would be no difference in this item. Practically there is, however, but with the result that a better track is obtained. The number of the sleepers has been assumed, therefore, at 1 400, 1 500, and 1 600 per kilometer (2 254, 2 415, and 2 576 per mile) for broad-, medium-, and narrow-gauge, respectively.

Quebracho ties are used almost exclusively on the Argentine railways; they are very hard and durable, and, owing to their high cost, are spaced rather farther apart than is usual in the United States. The average price, including freight, at Santa Fé, a fairly central point, for the area under consideration, is:

5 ft. 6-in. gauge	$1.90	each	=	$2 660	per	km.	$4 283	per mile.
4 ft. 8½-in. gauge	1.60	"	=	2 400	"	"	3 864	" "
Meter-gauge	1.20	"	=	1 920	"	"	3 091	" "

Laying and Surfacing.—This has been assumed to be somewhat more for medium- or broad-gauge, on account of the greater width, but, although it is a little doubtful whether this is really warranted, it is taken in order to be on the safe side.

Ballasting.—This is assumed to be the same for all gauges, for, in order to carry the same loads, a greater depth of ballast is required for narrow-gauge, where the loads are concentrated, than for the wider gauge. Then, again, the impact is greater on narrow-gauge, due to the greater height in proportion to the width of the rolling stock.

Yards and Sidings.—These are taken at a percentage of the cost of the track in each case. Here again, theoretically at least, there should be no increase in cost due to gauge, for, although the broad-gauge track costs more per linear foot, there is not so much of it required, broad-gauge trains of the same net tonnage requiring a lesser length of track than narrow-gauge trains. As, however, on lines of comparatively light or medium traffic the yards and sidings are likely to be made the same length in any case, the increase is made as shown.

Cattle Guards.—These will be slightly wider for wider gauge.

Miscellaneous Structures, etc.—Fences, Track Signs, Buildings of all kinds, Water Supply, Telegraphs, Docks and Wharves, General Expenses of Construction, Engineering and Legal Expenses, would not be changed.

Contingencies, Expenses of Promotion, Interest During Construction.—These are figured at percentages of the totals.

Equipment.—For the same amount of traffic, the equipment would probably cost slightly less for the wider gauge on account of the larger capacity of the cars, but, assuming as nearly as possible the same weight of engines, etc., this would not be a great deal.

Tables 15, 16 and 17 show the differences due to gauge alone on lines of light, medium, and heavy earthwork and bridging, and assuming the same traffic and carrying capacity on all. It will be noted that for lines of light and medium construction there is very little difference in the percentage of increase, what difference there is being a less percentage where the work is heavier, medium-gauge averaging 6% more than narrow-gauge and broad-gauge 10% more than narrow. For very heavy lines, that is, mountain lines with steep transverse slopes, there should be some additional increase in earthwork due to the increased width. This has been allowed for, and in this class of lines the medium-gauge might be assumed to cost 11% more and the broad 16% more than the narrow.

The summary of the totals is given in Table 14, in which the percentage is the increase above the cost of narrow-gauge.

TABLE 14.—SUMMARY OF COSTS.

Gauge.	COST PER MILE, IN GOLD DOLLARS.			COST PER KILOMETER, IN GOLD DOLLARS.		
	Light.	Medium.	Heavy.	Light.	Medium.	Heavy.
Narrow.....	$29 772	$54 760	$92 573	$18 458	$33 951	$57 395
Medium.....	31 581 + 6%	57 920 + 6%	102 892 + 11%	19 580	35 910	63 793
Broad.....	32 861 + 10%	60 430 + 10%	107 553 + 16%	20 374	37 467	66 683

It may be noted that the assumed increases in Table 14, which the writer believes to be the maximum or outside amounts, are not more than the usual allowances for contingencies in work of this magnitude.

COST OF CONVERSION.

The following estimate of the cost of changing the gauge, although not based on detailed surveys or calculation of quantities, is believed to represent average conditions, based on observations by the writer after an inspection of practically all the meter and standard-gauge

lines of the Argentine, as well as of a considerable proportion of the broad-gauge lines.

It is believed that it can be safely assumed that the cost of conversion, including a liberal allowance for rolling stock, will not exceed the figures given, and will probably be less. It is to be noted, however, that these estimates do not include any betterments, such as heavier rails, renewing bridges, etc., or any other works of improvement which it might be desirable to carry out at the time the gauge would be changed; but they do include an allowance for all new sleepers. It may also be noted that most of the lines which would be changed first are through easy country, and the cost would be less than the average.

TABLE 15.—Cost of New Construction.

Light Earthwork and Bridging.

	Cost per Mile, in Gold Dollars.		
	Meter.	4 ft. 8½ in.	5 ft. 6 in.
Right of way, station grounds, terminals	$40	$40	$40
Clearing	200	200	200
Earthwork	4 000	4 310	4 570
Bridges	2 000	2 150	2 300
Culverts	2 000	2 150	2 300
Track: Rails and fastenings, 70-lb. rail	4 000	4 000	4 000
Ties	3 090	3 860	4 280
Laying and surfacing	800	900	1 000
Ballasting, half earth, half stone	850	850	850
Yards and sidings, 20% of amount for rails, ties, laying, and surfacing	1 750	1 920	2 030
Cattle guards, fences, track signs	450	460	470
Buildings, shops, stations, section houses, water supply etc.	2 000	2 000	2 000
Telegraph and telephone	500	500	500
Docks and wharves	50	50	50
General expenses and administration	300	300	300
Engineering	1 000	1 000	1 000
Legal expenses	250	250	250
	$23 280	$24 940	$26 140
Contingencies, 5%; Expenses of promotion, 2%; Interest during construction, 8% — 15%	3 492	3 741	3 921
	$26 772	$28 681	$30 061
Equipment (rolling stock, etc.) assumed for same amount of traffic	3 000	2 900	2 800
	$29 772	$31 581	$32 861
Per kilometer	$18 458	$19 580	$20 374

TABLE 16.—Cost of New Construction.
Medium Earthwork and Bridging.

	Cost Per Mile, in Gold Dollars.		
	Meter.	4 ft. 8½ in.	5 ft. 6 in.

Bridges	10 000	12 000	13 000
Culverts	10 000	11 000	12 000
Track: Rails and fastenings, 70-lb. rail	4 000	4 000	4 000
Ties	3 090	3 860	4 280
Laying and surfacing	800	900	1 000
Ballasting, half earth, half stone	850	850	850
Yards and sidings, 20% of amount for rails, ties, laying, and surfacing	1 750	1 920	2 080
Cattle guards, fences, track signs	450	460	470
Buildings, shops, stations, section houses, water supply, etc.	3 000	3 000	3 000
Telegraph and telephone	600	600	600
Docks and wharves	50	50	50
General expenses and administration	500	500	500
Engineering	1 800	1 800	1 800
Legal expenses	300	300	300
	$77 020	$86 080	$90 220
Contingencies, 5% Expenses of promotion, 2% Interest during construction, 8% } 15%	11 553	12 912	13 533
	$88 573	$98 992	$103 753
Equipment (rolling stock, etc.) assumed for same amount of traffic	4 000	3 900	3 800
	$92 573	$102 892	$107 553
Per kilometer	$57 395	$63 793	$66 683

The author of the paper, Sir Frederick Robert Upcott, who gave these costs, estimated that the cost of changing the existing meter-gauge lines of India to 5 ft. 6-in. would be £2 500 ($12 500) per mile, or about £1 500 ($7 500) per kilometer.

It is stated* that the cost of changing the gauge of the lines in Queensland and West Australia from 3 ft. 6-in. to 4 ft. 8½-in. will be $111 000 000, or an average of $16 600 per mile ($10 000 per km.) for the 6 662 miles to be changed.

It has also been stated that the estimated cost of changing the gauge of the railways in Japan will be some $125 000 000 for about

* *Railway Age Gazette*, July 11th, 1913.

5 000 miles, or $25 000 per mile ($15 000 per km.). This seems high, but, of course, the topography of the country is quite rugged and mountainous and the railways have many large bridges and tunnels.

TABLE 18.—Estimate of Cost of Changing 1 Mile of Meter-Gauge to Medium- or Broad-Gauge.

Assuming Average Conditions on the Meter-Gauge Lines of the Argentine.

		Gold Dollars.	
		Medium.	Broad.
Right of way, station grounds, terminals, etc., $10 000 for additional terminal land for every 300 miles		$33	$33
Earthwork: Say, 5% additional for medium and 7% for broad on assumed present average cost of about $20 000 per mile		1 000	1 400
Bridges and culverts: lengthening		2 000	2 500
Track: Medium gauge:			
2 400 new sleepers at $1.60	$3 840		
New fastenings	250		
Taking up, relaying and surfacing	1 500		
		5 590	.....
Broad-gauge:			
2 600 new sleepers at $1.90	$4 940		
New fastenings	250		
Taking up, relaying, and surfacing	1 500		
		.....	6 609
Yards and sidings: 20% of main line		1 118	1 338
Cattle guards, nominal		15	15
Fences, track signs, etc., no change		.....	.....
Buildings, shops, stations, section houses, turntables, water supply. Will only involve changing tracks and spacing in shops, turntables, engine-houses, and running sheds, say $200 000 for every 300 miles		630	700
Signals and interlocking		75	75
Telegraph and telephone, no change		.....	.....
General expenses and administration		100	100
Engineering		250	250
Legal expenses		25	25
Interest during construction		600	700
Contingencies		600	700
		$12 036	$14 526
New rolling stock, say $5 000 per mile.			
Credit old rolling stock 3 500 per mile		1 400	1 600
Per mile		$13 436	$16 126
Per kilometer		8 330	9 998

Cost of Operation.

Various statements have been made in regard to the relative costs of operation and maintenance of lines of different gauges, almost invariably however, so far as the writer has been able to discover, based on comparisons of the costs on two existing lines or groups of lines. Such comparisons are not of great value, for no matter how generally similar two lines may be, or seem to be, the inherent differences in

physical condition, amount and character of traffic, rolling stock, management, policy, etc., will be considerable. An attempt was made by the writer to analyze the details of the operating costs of certain lines, and from this to form some idea of the actual effect on each item of a change or difference in the gauge, but it was found that there was so little information available that the result would be too much in the nature of a pure guess to be of any value, and as there seems to be no really good way of determining what actual effect a difference of gauge would have on the operation and maintenance costs, such comparisons between the results on lines of different gauges in various parts of the world as are available are given for what they are worth, followed by some discussion of the effect of gauge on maintenance of permanent way and an analysis of the possible economies by the use of heavier rolling stock, etc., both in maintenance of equipment and costs of operation.

Indian Railways.—In regard to the railways of India, the following statement was recently made by Sir Guilford Molesworth, showing that although the train-mile costs on the narrow-gauge lines of that country were lower than on the broad, the net ton-mile costs were higher.

Taking the East India Railways (5 ft. 6-in.) as 100, the costs on the following narrow-gauge lines were:

	Per train-mile.	Per ton-mile.
Assam Railway	71	315
South Maharatta	56	280
Burma Line	64	290

A statement prepared by Sir Frederick Upcott, giving the comparative statistics of eight of the principal broad-gauge and eight of the principal narrow-gauge lines, for 1903, showed that, though the earnings on the narrow-gauge lines gave practically the same returns on the capital invested as on the broad-, the average charges were:

	Cents, in gold.	
	Broad.	Narrow.
Per passenger-mile	0.42	0.40
Per freight-mile	0.92	1.14

and the cost of carriage of freight per ton-mile was:

0.5 cent for the broad-gauge.
0.6 " " " narrow-gauge.

It is interesting to note, here, that the average weight of trains on the broad-gauge was 167 tons, as compared with 88 tons for the narrow-gauge.

Australian Railways.—The ton-mile costs in Australia are not available, but the train-mile costs for 1910-11 were as follows:

Broad	$1.20
Medium	1.09
Narrow	1.32

These figures, taken together with the fact that the net earnings per mile of the medium-gauge lines were double those of the narrow-gauge, indicate the inferiority of the earning power of the latter.

Argentine Railways.—In the Argentine the average operating costs of all lines for 1909 were as follows:

	Broad.	Medium.	Narrow.	Broad.	Medium.	Narrow.
	Per train-kilometer.			Per train-mile.		
Dollars, gold....	$1.006	$0.755	$0.876	$1.620	$1.216	$1.410
	Per ton-kilometer.			Per ton-mile.		
Cents, gold.....	0.928	0.957	0.967	1.494	1.540	1.557

The ton-mile (ton-kilometer) used for these figures is that of the "peso util" or "paying weight" transported, and includes passengers, with ordinary baggage, calculated at 100 kg. (220 lb.) each, excess baggage, and express, as well as freight; but, as the proportion of revenue from passengers, baggage, and express is much greater on the broad-gauge lines, being 31% of the total as compared with 19% for the narrow-gauge, the comparison is hardly fair to the broad-gauge. It shows, however, the same tendency to low cost per ton-mile for the wide-gauge, although the train-mile costs, due to the heavier trains hauled, are higher.

It is to be noted, as previously stated, that the medium-gauge lines, do not offer any real comparison on account of local conditions, and this applies also to the ton-mile costs on these lines, which are given later.

Taking the figures as they stand, and using the number of ton-kilometers for 1909, they show a saving in operating costs of a little more than $100, gold, per kilometer ($160 per mile) per annum in favor of the broad-gauge, which, of course, is not very large. In discussing these costs, however, consideration must be given to the essential difference and physical characteristics of the broad- and narrow-

gauge lines at this time (1909). The narrow-gauge lines of the Argentine were then doing a fair amount of business, as more or less local lines, that is, none of them reached the National Capital nor did they partake of the character of trunk lines. The Central Cordoba was then building to Buenos Aires, and now (1911) all the narrow-gauge lines realize that, if they are not to be entirely crowded out, they must get in close touch with the National Capital in order to stay in business, and spend large sums for capital account to put their lines in condition even to meet reasonably the competition existing or to be expected. The narrow-gauge lines were then capitalized at about $28 000, gold, per km., as compared with $42 000, gold, for the broad-gauge, but they are now faced with the necessity of capital expenditure which will bring them well up toward the capitalized value of the broad-gauge. A large part of the capital of the latter is invested in the expensive Buenos Aires terminals, and other facilities at all points on their lines, which they have found it necessary to have in order to do their business, which the narrow-gauge lines have yet to acquire and develop, and on the capital expenditure for which they must earn the interest. It is also quite certain that many of the narrow-gauge lines would have to be double-tracked in order to handle the business.

If it could be assumed that the foregoing figures would hold good for any amount of business to be hauled, they would not present a very formidable argument for the broad- as compared with the narrow-gauge, but all railroads, as well as all other enterprises in any country as progressive as the Argentine, must grow with the country or be crowded out, and this is what is beginning to happen to the narrow-gauge lines. The business coming to them is more than they can handle economically with the plant they have, because it tends to cause congestion.

The need of adequate facilities for doing business and the increased cost of operation due to their lack when the amount of business offered passes a certain limit, was shown in 1906 in the United States, when many of the railroads of the country suffered serious losses because of the congestion caused by the large amount of freight offered for transportation which they had not the facilities for handling.

The real test, of course, is the final net earnings on the investment, and here the broad-gauge lines, in spite of their heavier capitalization,

are a long way ahead, with average earnings of 5.66% on the capital invested, as compared with 2.41% earned on the capital invested in the narrow-gauge lines, so that it is evident that the ton-mile figures do not tell the whole story.

Taking freight alone, on the basis of these 1909 figures, the receipts per ton-mile make a still better showing in favor of the narrow-gauge, the averages being:

	Freight receipts.	
	Ton-kilometer.	Ton-mile.
Broad,	1.17	1.95 cents, gold.
Medium,	1.26	2.10 " "
Narrow,	1.05	1.75 " "
Average for all lines,	1.15	1.92 cents, gold.

It may be noted, also, that the rates on the Central Cordoba and Santa Fé lines are the lowest of any lines in the country, and it is these which tend to lower the average for the narrow-gauge lines, but it is believed that the explanation given above shows the reason for the apparent cheaper cost of operation, or, rather, lesser rates on these two narrow-gauge lines. It may also be added that the property of neither has been kept in first-class physical condition, and, as already stated, their net earnings show a much lower percentage of the capital invested than do the broad-gauge lines. The Government lines, also, which are narrow-gauge, are operated at a loss. If the freight charges on these lines were fixed to give the same return on the capital invested they would, of course, be much higher.

Comparison of Ton-Mile Costs.—The average receipts per ton-mile of the Argentine railways in 1909 are given above. The average for the United States in 1912 was 0.85 cents. On 70% of all the railroads the average was less than 1.0 cent per ton-mile, and the lowest average rate was 0.48 cent per ton-mile.

The actual cost of moving freight on the Bessemer and Lake Erie Railway in 1909 was stated to be* 0.230 cent per ton-mile; this included terminal charges on a road only 144 miles long; adding interest on the investment would bring the total cost to 0.280 cent per ton-mile.

Maintenance of Permanent Way.—In regard to maintenance, it seems quite evident that this would be considerably more on narrow-

* *Engineering News*, April 21st, 1910.

gauge lines having any large amount of traffic, and especially if it was desired to run passenger trains even at reasonably fast speeds.

If it were possible to build and maintain a track without inequalities, or if the inequalities of the line and the forces tending to produce oscillation could be reduced in the same proportion as the width of the gauge, the cost of maintenance might be considered as proportional to the width, but these conditions are unattainable.

The narrower the gauge the greater is the angle through which the vehicle is canted laterally through a certain depression or elevation of one of the rails, and the greater, therefore, is the inequality produced in the loads on the springs on opposite sides, and, consequently, on the two rails also, so that the narrower the gauge the greater the extent of lateral oscillation to which any given inequality in the line will give rise, and this is a point of especial importance in districts where, from the variations of climate or other influences, the permanent way is likely at times to get more or less out of repair.*

It is to be noted, also, that the use of stone ballast is almost indispensable on narrow-gauge lines, in order to have track on which speeds of more that 30 miles per hour are safe, and that the depth of the ballast must be increased in order to distribute properly the loads which, in the narrow-gauge, are concentrated on a smaller area.

A few years ago it was quite generally thought that the principal function of the ballast was to afford proper drainage for the track, though even as long ago as 1887-90 experiments, which were conducted in Germany by Railroad Director Schubert, had indicated the value and necessity of ballast for the proper distribution of the loads. In view of the great increase in axle loads in recent years, an extended series of experiments was made in 1908-10 by the Pennsylvania Railroad to obtain further light on this phase of the subject.† These experiments showed quite clearly and conclusively the part played by ballast in the distribution of the loads, and the necessity of a sufficient depth to take care of this. It is quite certain, therefore, that the concentration of loads on lines of narrow-gauge, both by reason of the smaller bearing area of the sleepers and the additional impact due to the higher center of gravity and greater oscillation, must be taken care

* See also p. 566 *et seq.*

† *Proceedings*, Am. Ry. Eng. Assoc., 1912.

of by an increase in depth of ballast, if equally good results are to be obtained.

Maintenance of Equipment.—It is quite difficult, if not impossible, to make any estimate of the effect of gauge on the cost of maintenance of equipment. It is quite sure that the cost of maintenance of both locomotives and wagons is not proportionate to either their size or capacity, that is to say, it does not cost twice as much per annum for the maintenance of a 200-ton engine as it does to maintain a 100-ton engine; two 25-ton cars will cost more to maintain than one 50-ton car doing the same work. The passenger equipment for narrow-gauge has only about three-quarters of the carrying capacity of the broad-gauge for vehicles of the same length, so that, to do the same amount of business, there will be a larger number of vehicles, larger proportion of dead weight per passenger, and, therefore, a larger cost of maintenance per revenue unit.

If it could be assumed that all or even the greater proportion of the business of the Argentine, if carried on broad-gauge lines, could be handled by locomotives and in freight cars of twice the capacity of those now in general use on the narrow-gauge, one could say at once that the cost of maintenance of equipment would be greatly lessened thereby. This, however, is not the case, and there are many locomotives and cars in use, and of a useful size, on the narrow-gauge, equal in capacity to many on the broad-, and it is only a certain proportion of the business that can be handled to better advantage in cars and by locomotives of larger capacity.

Taken altogether—passenger cars, freight cars, and locomotives—it seems quite sure than the cost of maintenance of equipment would be more on narrow-gauge lines than on the broad-gauge, by reason of the larger number of vehicles required to handle the same amount of business. Just how much this item would amount to it is not possible to say, though the figures in Table 19 may give some idea.

Effect of Larger Rolling Stock Units on Costs of General Repairs.—Assuming quite conservatively that half the business could be handled on the broad-gauge by equipment having 50% greater capacity than that now in use or possible on the narrow-gauge, then the number of units of rolling-stock would be reduced one-sixth. The cost of repairs on the larger units would be somewhat greater, but not propor-

TABLE 19.—Cost of Maintenance of Locomotives and Cars in 1909 on the Narrow-Gauge Lines of the Argentine.

	Number in service.	Repairs and Maintenance.	
		Total cost.	Cost, each.
Locomotives	500	$1 051 332	$2 102
Passenger coaches	599	258 477	430
Baggage cars	402		
Freight cars	13 540	683 175	47
Service cars	540		
		$1 992 984	

tionately so, say, roughly, only 50% of the increase. That is, for example, taking the case of the locomotives, 250 would remain as at present, each costing $2 100 a year for repairs, the other 250 would be replaced by two-thirds of the number, each unit having 50% greater capacity and costing 25% more for repairs, that is, there would be 167 each costing $2 625 for repairs per annum. The total cost of repairs would then be:

Locomotives	250 ×	$2 102 =	$252 500
	167 ×	2 625 =	438 375
Passenger coaches	300 ×	430 =	129 000
	200 ×	537 =	107 400
Freight cars, etc.	7 240 ×	47 =	340 280
	4 826 ×	59 =	284 734
			$1 825 289

This shows a saving of $167 695 per annum, equal to about $23 per km. of line, with the business of 1909. With a live policy of operation, the building of branches to develop the existing main lines, it is not unreasonable to assume that, by 1919, say in 10 years, the business will be increased to three times the present amount, and a large proportion of it will need to be handled in heavy trains.

There would be all the new mileage on which there would be a similar saving to that just shown, the new mileage would bring as much business to the old lines as these now have, and the natural increase in the country adjoining the old lines might be at least equal to the business now, so that on this item of repairs alone there would be a saving of from $70 to $100 per km. on the present lines, and at

least $20 to $30 on the new lines, or, say, an average of $50 per km. per annum on the whole system then in operation.

It is to be noted that if the change of gauge is brought to pass, the new equipment, if properly selected, would show a much smaller cost of repairs, as it would be better adapted to the requirements of the service. There would be also, without going to extremes, much of it of double the average capacity of the present narrow-gauge rolling stock, instead of only 50% greater as just assumed, so that the foregoing estimate is quite conservative.

Effect of Small or Large Cars on Train Resistance, Loading, Etc.— The effect of small cars on train resistance has already been pointed out.* Their effect on the cost of operation is indicated by the following:

Assume an engine of the Mikado (2-8-2) type:

Total weight of engine and tender..	246 600 lb.
Weight on drivers.....	110 500 "
Maximum tractive power.....	28 900 "

This is about as large an engine as can be built for meter-gauge of a type which will give large power capacity with ability to make fairly good speeds with heavy trains.

Engines of the Mallet or articulated type are built of much greater power, but, as that type only operates efficiently at very low speeds and is best adapted to sections of heavy gradients, it does not afford as good a basis for comparison for general conditions, in fairly easy country, similar to that found in the Argentine, where much of the freight must be moved quickly, as does the Mikado type.

The tonnage-rating formula of the American Railway Engineering Association is

$$R = 2.22\,T + 121.6\,C.$$

in which

R = Total resistance on level tangent, in pounds,
T = Total weight of train behind the tender, in tons,
C = Number of cars.

This assumes good, fair rolling stock and track, and that the resistance does not increase at ordinary freight train speeds between 7 and 35 miles per hour.†

* p. 590.
† *Proceedings*, Am. Ry. Eng. Assoc., 1910.

Using this formula and applying it to trains of fully-loaded cars on a line with grades of 0.6%, it is found that the engine assumed, when working to full capacity (*i. e.*, exerting the same power in each case), can haul the loads shown in Table 20.

TABLE 20.

	No. of cars.	Net tons per car.	Tare per car, in tons.	Gross tons.	Net tons of freight.
Broad-gauge cars	24	50	18	1 632	1 200
Standard-gauge cars	24	50	18	1 632	1 200
Meter-gauge cars	34	33	13	1 564	1 122

This is an increase of 78 net tons per train, as between meter- and standard-gauge. The formula deduced by Professor Schmidt, of the University of Illinois, from the results of extensive experiments made to determine the influence of car weight on train resistance, shows quite similar results, though even less favorable to the lighter cars.

The average receipts per ton of freight per kilometer in 1909 were 1.15 cents, gold. For the train under consideration, therefore, the average increased receipts for the same operating costs per train-kilometer would be 89 cents, gold, or, with an average goods traffic of one train daily each way, $1.78 per km. per day, or about $500, gold, per km. ($830 per mile) per annum.

It is stated that some of the traffic in the Argentine can be handled better in cars of small capacity. Assuming that half the business is handled in small cars on which there is no saving, there would still be an increased income of $250, gold, per km. per annum, due to the use of the larger cars.

Assuming, then, that an average kilometer of broad-gauge line costs from $3 000 to $5 000, gold, more to build than meter-gauge, the investment is warranted from this standpoint alone, and, taking the figures at the end of the paper, the change of gauge of the existing lines would also be warranted.

The foregoing takes no account of the further saving which may be effected on the wider gauge by the use of larger engines than are at all possible on meter-gauge, thereby further increasing the size and weight of trains and, consequently, obtaining lower operating costs, nor the fact that the speed of passenger trains is limited on the narrow-

gauge, both on account of the size of the engines and the lesser stability of trains.

Economy in Increased Train Loads by Reduction in Number of Trains.—The possibilities of the use of the larger cars and heavier engines depends, of course, to a large extent, on the kind of traffic to be handled. Such articles as cereals, cattle, timber and other forest products can all be handled to better advantage in large cars. The tonnage of these articles handled on the narrow- and medium-gauge lines of the Argentine in 1909 is shown in Table 21.

TABLE 21.

	Narrow.	Medium.
Cattle	219 631	232 680
Wool, hides, etc.	40 864	38 278
Cereals	955 448	294 659
Sugar	223 789	3 528
Minerals	35 500	.....
Construction material*	2 153 312	140 360
Firewood	768 828	30 045
Charcoal	302 881	33 495
	4 700 253	773 045

* Includes forest products.

That is, about 5 500 000 tons, out of a total of 8 500 000 tons, were handled on these lines, or 65% of the total. The average haul on all freight in 1909 was about 180 km., and the total length of lines about 9 000 km. It may be noted, also, that with the opening of the through connection to Paraguay and the extension of a railway line through Missiones, the shipment of timber suitable for building purposes from these northern points to the south is likely to assume large proportions, and this will all be long-haul business which must be handled cheaply to make it move.

The Mikado engine previously referred to can haul, say, 1 000 tons of net load on 0.6% grades. The largest engine yet built for narrow-gauge, the Mallet (articulated) engine previously referred to, might haul, say, 2 000 tons net load. There are, however, on some parts of these lines, especially in the southern section of the Central Cordoba and all through the Provinces of Entre Rios and Corrientes, grades of 1.0% or heavier. Taken altogether, therefore, considering the grades, the fact that the big articulated engine is not a useful type for

general use, and that a certain number of engines of the Mikado type must be kept in use for general freight services, it seems safe to assume that, even under the best of conditions on the narrow-gauge lines, the heavy trains will not exceed an average capacity of 1 500 net tons, whereas on the broad- or medium-gauge this could be doubled.

The operation of such extremely heavy trains, however, is not a practical proposition in the Argentine at present, nor is it likely to be in the immediate future, though the increasing distances to the new areas constantly being opened up will continually increase the tendency in this direction.

In referring to trains of this weight, it must not be assumed that the very much less average weight of trains has been lost sight of, the average net train loads in the Argentine in 1909 having been:

Broad	327	tons.
Medium	198	"
Narrow	211	"
All lines.....	293	"

The average train loads in the United States in 1910 for all lines was 380 tons, and in Group II, comprising the States of New York, Pennsylvania, and New Jersey, 502 tons, yet there are records of single trains of more than 8 000 tons gross, and the great reduction in the cost of transportation, which has been obtained in the United States in spite of the high cost of labor, has been brought about by the use of heavy trains for bulk traffic which can only be moved profitably at low rates.*

For the purpose of this argument, therefore, and to get some idea of the possible savings due to the reduction in the number of trains, it is entirely reasonable to assume that the practical train loads for the broad-gauge may easily be one-third greater than on the narrow-gauge, or say, 2 000 net tons, as compared with the possible maximum of 1 500 tons on the narrow-gauge.

Taking into consideration the growth of the country and a continuance of the railway development, it might be assumed that within a few years the amount of this class of traffic on the lines under consideration will be doubled to, say, 12 000 000 net tons. On the medium-gauge, with train loads of 2 000 net tons, this would mean 6 000 trains,

* See also p. 581.

and the narrow-gauge would require 8 000 trains. The average haul on this traffic is now 180 km., and the length of haul is practically certain to increase. An average engine division is about 150 km., and, considering the almost certain increased length of haul, one should add, say, one-third more to the number of trains (that is, train runs handled by one crew), making the numbers 8 000 and 10 667.

The present actual operating cost, that is, cost of coal, lubricants, train crews, repairs to rolling stock, etc., is about 50 cents, gold, per train-kilometer, of which about one-third is for fuel and water. This, however, is with trains very much lighter than those under consideration. With heavier trains the fuel and water would be increased, approximately, directly in proportion to the weight of the train. Repairs would be affected somewhat more, but not in proportion.

The average present train load to which these figures apply is about 500 tons. So taking this cost of 50 cents, of which, say, 15 cents is for fuel, water, and lubricants, and multiplying these items by three, and increasing the remainder by 25%, gives the following cost per kilometer per train of 1 500 tons:

Fuel, etc.....	15 cents	× 3	= 45	cents.
Other items..	35 "	+ 25%	= 44	"
Total.....			89	cents per train-kilometer.

In increasing the weight of the train from 1 500 to 2 000 tons, the other items would not be affected as much as by the increase as above from 500 to 1 500. Fuel might be increased 33%, though this is doubtful,* and the other items hardly at all, but, say, 10 per cent. We have, therefore, for a train of 200 tons:

Fuel, etc.....	45 cents	+ 33%	= 60	cents.
Other items...	44 "	+ 10%	= 48	"
Total.....			108	cents per train-kilometer.

Taking the average run as 150 km., the cost per train would then be:

For trains of 1 500 tons, 150 km. × 89 cents = $133.5 per train.
" " " 2 000 " 150 " × 108 " = 162.0 " "

and there would be:

On the narrow-gauge	10 667	trains at	$133.5	= $1 423 912
" " medium-gauge	8 000	" "	162.0	= 1 296 000
				$127 912

*See p. 584 *et seq.*

or equal to about $14.20 per km. of line, due to the reduction in the number of trains.

In the foregoing calculation it has been assumed that the costs of fuel, water, and lubricants increase directly in proportion to the weight of trains, but most of the larger modern engines have shown a marked economy in this respect, and the coal consumption, etc., has been quite a little less, proportionately, to the work done.

It may be noted that, in making these assumptions, it is not considered that there will be any additional costs on the standard-gauge, due to the operation of the heavier trains, which in some cases have to be considered. It is believed that a 1 500-ton train will be quite as destructive to the track on the narrow-gauge as a 2 000-ton train on the medium-gauge, and that the time factor will not enter into the question, as an engine designed to haul a 2 000-ton train on standard-gauge will make as good time and with less effort than will a narrow-gauge engine designed to haul 1 500 tons, on the same grades and alignment.

The Necessity of an Efficient Transportation Machine.—The possibility of the competition of other broad-gauge lines or of river transportation has been referred to, and it must be kept constantly in mind that cheap, but at the same time efficient, transportation is a necessity, both for the development of the country and on account of the river competition.

The following quotation from a recent review of the general railroad situation in the United States by M. C. Colson, an eminent French engineer, shows how cheap railroad service has affected transport by water, and has a direct bearing on the necessity of establishing a railway system in the Argentine, which will accomplish similar results there. It hardly seems possible with the narrow-gauge to approach the low cost of transporting bulk freight which can be achieved on the medium- or broad-gauge.

After pointing out that the mileage of railways in the United States amounts to 10% more than that of all the railways of Europe, though the population is only 90 000 000, as compared with 450 000 000 in Europe, he states:

"Before the railways [of the United States] became developed, attempts were made to extend the inland waterways by constructing many canals, but inland navigation gradually died out, except on the Great Lakes, where it has a quasi-maritime character, and on some

exceptionally placed waterways, as soon as a better sytem of transport became known. It was the railway which made it possible to develop with unexampled rapidity this great continent, to develop farms whose produce, sent to the Old World at very low prices, there produced the agricultural crisis of thirty years ago. Then it helped to extend a population there which will very soon consume all the produce of its own country, so that its growth is an important factor in the general rise in prices, which is now producing with us a crisis in an inverse sense of the former one, namely: the dearness of food. Finally, the railways, which carried coal and minerals at rates even lower than those charged for cereals, helped to give the United States an industrial development, the general growth and magnitude of which are just as surprising as the former development of farming."

Statistics are then given showing in detail the much lower costs of transportation in the United States as compared with those of Europe,* and he continues:

"In Europe 10-ton wagons are still the rule, 20-ton wagons are exceptional, and 40-ton wagons are very rare. In the United States, out of 2 400 000 wagons, there are only 12 000 which take less than 18 tons, and most can take 18 to 33 tons; 634 000 can take 33 tons, and 390 000 can take 42 to 54 tons. These working conditions, which have resulted in the historical development of American farming and industries, make it possible to have very low rates and still work at a profit."

SUMMARY.

The preceding discussion may be briefly summarized as follows:

Curvature.—Within the limits of the practical operation of railroads, a curvature of any radius which is feasible on meter-gauge is as practical on 4 ft. 8½ in., or even 5 ft. 6 in.

Gradients.—The working of trains on steep gradients is not affected by gauge, except in so far as the narrow-gauge cuts down the locomotive capacity, and is, therefore, at a great disadvantage.

Location.—In view of the foregoing, the narrow-gauge (3 ft. 0 in. to 3 ft. 6 in.) does not permit better adaptability of the alignment to the conformation of the ground.

Cost of Construction.—This is so little more for 4 ft. 8½ in. as to be more than counterbalanced by economy in operation.

Speed.—This is an important feature in railway operation which is adversely affected by narrow-gauge.

---

* See also the statement on p. 581.

Stability.—The relative stability of narrow-gauge trains in motion is much less than that of trains on medium- or broad-gauge; consequently, high speeds are impractical and may be dangerous.

Track Stresses.—Much higher track stresses are produced on the narrow-gauge; there is greater impact and therefore more difficulty in maintaining track on narrow- than on broad-gauge.

Rolling Stock Cars.—The greater width of narrow-gauge cars in proportion to the gauge is considered a necessary evil rather than an advantage, and it is shown that there is probably no advantage to be gained by making the broad-gauge cars any wider than they are at present. In the matter of passenger cars, the narrow-gauge is at a decided disadvantage, both as to cost per unit of accommodation and in dead weight per passenger. In freight cars, there is little difference in cost, within the limits of size possible on the narrow-gauge, though cars of twice the capacity are available for medium- or broad-gauge. The increase in weight of modern freight trains, in order to decrease the cost of operation, has made heavier draft rigging necessary, thus tending to increase the proportion of dead to paying load to a much greater extent on small capacity cars than on the larger ones, than has been the case heretofore.

Locomotives.—The cost per unit of capacity of locomotives is about the same for each gauge up to the limit of the narrow-gauge, which limit for all types is about half of that of the 4 ft. 8½-in. or 5 ft. 6-in. There is an economy in the use of heavier types of locomotives not available for the narrow-gauge, and the use of cars of large capacity is a necessity for cheap transportation.

Train Resistance.—Train resistance is decreased by the use of larger units.

Capacity.—Figures are given tending to show that the relative capacity of narrow-gauge lines is not more than half that of medium- or broad-gauge.

Heavier Engines and Trains.—There is a general discussion showing the part played by increase of train loads in reducing costs in the United States.

Cost of Operation.—The ton-mile costs, on both Indian and Australian Railways, as well as those in the Argentine, are less on the medium- and broad-gauge than on the narrow-gauge, although the train-mile costs are often higher.

The lowest ton-mile costs on any railway in the Argentine are more than twice as high as any in the United States.

The saving in cost of operation, due to the use of larger cars and heavier trains, is considerable, and would in itself go a long way toward meeting the interest charge on the additional cost of the wider gauge.

Cost of Maintenance.—Maintenance of way probably costs more per traffic unit on narrow- than on medium- or broad-gauge on any but lines of very light traffic.

Maintenance of equipment should be less on medium- or broad-gauge by reason of the larger capacity, and, consequently, lesser number, of locomotives and vehicles, provided there is business to warrant their use.

Need of Efficient Transportation Machine.—The necessity of an efficient transportation machine to develop the country properly is pointed out, as well as the part played by the railways in developing the United States, the country most nearly comparable with Brazil and the Argentine.

The Most Suitable Gauge.

We now come to the consideration of the most suitable gauge for the development of these countries. Such details of the topography, general conditions, traffic, etc., as are necessary for a proper understanding of the requirements are given in Appendix B.

In the Argentine, as in India and Australia—the only other countries which have large areas, large traffic, and different gauges—whatever the cause may be, however different any two lines may be, it is a fact that the greatest development has been along the lines of the broad- or medium-gauge railroads, and the big business is done by them. This is shown in Table 22.

TABLE 22.—Receipts, in Gold Dollars, per Mile of Railway per Annum.

Country.	Year.	Gross Receipts.			Net Receipts.		
		Broad.	Medium.	Narrow.	Broad.	Medium.	Narrow.
Argentine	1911	$7 385	$3 450	$3 905	$2 340	$1 395	$1 000
India	1906	9 870	.....	3 910	4 845	.....	2 090
* Australia, Government	1911	6 985	8 135	3 515	2 565	3 165	1 190
Australia, Private	1911	2 040	3 850	2 510	1 000	3 055	1 150

*Leaving out South Australia, total receipts $26 700 for two gauges not divided; and Northern Territory, $1 875 narrow-gauge, too small to be averaged with others.

It is difficult to get close figures for Brazil, but for 1906—the latest for which official statistics are published—the three systems which contain among them the broad-gauge lines, namely, The Central of Brazil, The Paulista, and the São Paulo Railways, operate (counting both broad- and narrow-gauge) less than 15% of the total mileage of the country, and their receipts amount to nearly 65% of the total, averaging about $12 000 per mile of line.

Considering the actual experience of the other countries, therefore, and the preceding detailed discussion of the actual effect of gauge, there seems, to the writer, to be little opportunity for a difference of opinion that the 4 ft. 8½-in. gauge is the most suitable for almost all conditions, and that for new lines, even in, or perhaps more particularly in, mountainous districts, and where the amount of business to be expected is not large, the slight difference in cost is generally more than warranted by the possibilities of economy in operation. The question in the Argentine and Brazil, however, is whether the cost of changing the existing narrow-gauge lines is warranted, and, in the former country, whether the change should be to 4 ft. 8½ in. or to 5 ft. 6 in., and, by the adoption of this latter, unify the gauge of all the lines in the country.

The consideration of a change of gauge, if confined to the Argentine alone, is practically narrowed down to the question, whether it is possible to unify the gauges of all the railroads, or whether one gauge shall be eliminated, leaving only two instead of three? The following argument, as far as page 626, therefore, is confined to a consideration of the question as it affects the Argentine, and without reference to the adjoining countries.

The Best Gauge for the Argentine Alone.—The relative advantages of 4 ft. 8½ in. and 5 ft. 6 in. have been discussed at some length, and it is believed that it is shown fairly conclusively that 5 ft. 6 in. does not now (with the imposed restrictions as to loading gauge in the Argentine) offer any advantages, from a purely transportation standpoint, over 4 ft. 8½ in., nor would it be likely to, even if there were a possibility of taking full advantage of the extra width of gauge by designing rolling stock with the same proportionate overhang. It seems important to emphasize this latter statement, as it is generally supposed that the 5 ft. 6-in. gauge could be better utilized if full advantage were taken of the extra width, but this is not the case,

or, at least, only in a minor degree, and, if the 5 ft. 6-in. gauge is adopted, it will not be for any advantage it has over 4 ft. 8½-in., but solely in order to unify the gauges of all the lines in the Argentine.

It is a safe assertion that it is impracticable to work more than two different gauges, inasmuch as all lines must have access to the ocean ports, and although it is practical to work two gauges, by having a third rail, on the port railways, it is not practical to work three, and it is impractical to reserve a special section of a port for a special gauge.

The broad-gauge is undoubtedly there to stay, as it has the greatest mileage, the companies working it are by far the strongest financially in the country, and, to a large extent, are all controlled by mutually friendly interests which probably would not even consider a proposition to narrow the gauge.

The meter-gauge has the next largest mileage, nearly four times that of the medium-gauge, and it would be far more costly to convert the meter-gauge lines to medium- than *vice versa*. It seems, therefore, as if, between these two—the meter- and the medium-gauge—the medium might have to go. This would be particularly unfortunate, as it would be undoubtedly a long step backward, but there are many indications that a sentiment is rapidly growing against the existence of the three gauges.

The Government lines, all meter-gauge (except those in Patagonia which are 5 ft.-6 in.), have been built with the primary object of bringing the outlying sections of the country and the capitals of the Northern Provinces in touch with the National Capital, for both political and military reasons. They reach every provincial capital, except Entre Rios, Corrientes, Mendoza, and Buenos Aires, and are connected with the latter, the National Capital, by two separate lines of meter-gauge, the Central Cordoba and Compañia General de Buenos Aires, so that every capital (except Mendoza) and practically the whole of the northern end of the Chilian frontier and the frontier of Bolivia can be reached by through trains from the capital without change of coaches.

The frontiers of Paraguay, Brazil, and Uruguay, where they join the Argentine, can only be reached by the medium-gauge, and, though this gives access to them from the National Capital itself, if it becomes necessary to send troops to any of these frontiers, all, except those from the City of Buenos Aires and vicinity, would have to be transferred from cars of a different gauge. This, though it may appear to

be a far-fetched argument for changing the gauge of the Entre Rios and North East Argentine Railways to narrow-gauge, at least partly explains the growing sentiment that the Government should be able to reach these frontiers over lines of the same gauge which now enables it to reach every other part of the country except Bahia Blanca, and access to this latter by a meter-gauge line is only a question of time, if the rest of the meter-gauge lines remain as they are. The experience of Japan (see page 639), however, shows the inferiority of the narrow-gauge for military purposes.

There is also the feeling of the people of these two provinces, Entre Rios and Corrientes, that they are isolated. So long as their railroads stopped at the edge of the rivers, and they were obliged to leave the train and cross the water in some kind of a boat, they accepted that as inevitable. The opening up of the Entre Rios car-ferry route to Buenos Aires, however, has completely changed the aspect of the province, and has shown its inhabitants the great advantage of through railway communication, so that they will not be satisfied until they have the same kind of through communications with the great northern section of the country, Tucuman, Bolivia, and the Chaco, by car-ferry transfers between Parana and Santa Fé and between Corrientes and Resistencia.

From Santa Fé there are narrow-gauge lines reaching practically the whole country except the Cities of Bahia Blanca and Mendoza. It is extremely natural, therefore, that it should be proposed, as it is quite seriously, to cover the whole of the Provinces of Entre Rios, Corrientes, and Missiones with a network of narrow-gauge lines connecting at Parana and Santa Fé with the narrow-gauge net on the other side, or to have the Government take over the existing line and change the gauge to meter.

It seems to the writer, however, that these proposals are made without an adequate realization of what an efficient transportation machine is, and what it means to the future development of the country. The need of fairly rapid transportation for passengers, the character of the freight traffic, etc., are indicated in Appendix B.

The principal defect of the narrow-gauge, which has been already pointed out, is its much lesser stability and greater stresses, both to rolling stock and track, caused by the unevenness of the latter, combined with the much greater height in proportion to the width of support of the former. This makes stone ballast—a very expensive article in

the Argentine—an absolute necessity for the narrow-gauge, whereas the broad- and medium-gauge, in many cases, can handle the traffic fairly comfortably without it.

In considering the merits of the two gauges, there seems to be little need, at this late day, to prove that the narrow-gauge, as a transportation machine, that is, regarded solely from the standpoint of a machine for the safe, comfortable, rapid, and economical transportation of passengers and freight, is inferior to medium or broad. Even the most ardent advocates of narrow-gauge admit the inferiority, but claim that this is compensated by the lower first cost, and also, sometimes, that narrow-gauge lines are cheaper to operate.

The statement that narrow-gauge lines are cheaper to build is fallacious, but still persists in some quarters, because many narrow-gauge lines actually are built more cheaply than some medium- or broad-gauge lines. This, however, is not because they are narrow-gauge—at least not to any great extent, as has already been shown in detail—but because they are built of cheaper materials. They have lighter or lesser capacity. For the majority of the lines to be built in the Argentine, which will cost mostly less than $25 000 per km., the costs would be, approximately, for the same type of construction and including all interest and overhead charges:

Narrow-gauge, per kilometer	.....	$25 000,	gold.
Medium-gauge, " "	.....	27 500	"
Broad-gauge, " "	.....	27 750	"

There will be many hundreds of kilometers costing not more than $15 000, on which the difference would be even less.

The mistake most often made in discussing this question is in confusing the terms "Narrow-gauge railway" and "Light railway," though, of course, a "Light railway" may be of any gauge.

In some of the discussions on this phase of the subject, it has been claimed that if standard- or broad-gauge roads or branches were built with light rails, bridges, etc., it would not be possible to use the same rolling stock on them that is used on the main line, or lines of heavier construction, but this can hardly be supported. It must not be forgotten that the force of impact due to speed is a most important factor, governing the necessary strength of the track and other structures of a railroad, and though one would not expect to run the heaviest type of

locomotives over a light line, it is perfectly feasible to carry any rolling stock, except the heaviest locomotives, at low speeds on rails as light as 40 lb., and there is no economy in building bridges for any railway traffic that will not carry freight cars of 50 tons capacity running at speeds of 20 miles per hour, which is quite fast enough for branches of light traffic.

In regard to cost of operation, there is room for difference of opinion, as it seems to be impossible to offer proof of the actual effect of gauge on this. The matter has been discussed in some detail, and there seems to be no reasonable doubt that, assuming equal conditions, the cost would be less on the broad-gauge than on the narrow-, but, just how much, it would be difficult to say. Certain of the figures seem to show that the saving made possible by the use of larger rolling stock might alone be more than enough to compensate for the cost of conversion.

The problem, therefore, so far as only the Argentine is concerned, seems to be narrowed down to the question of either the unification of the gauge by conversion of all lines to 5 ft. 6 in., or of changing all the narrow-gauge lines to medium, or all the medium to narrow, and in any case the scheme adopted must embrace all the lines of the gauge to be changed. So far as having an efficient transportation machine is concerned, the problem would be solved by the conversion to the medium-gauge, but if this is to be considered seriously, the question naturally arises would it not be throwing away a great opportunity to go farther and convert all to 5 ft. 6 in., and so unify the gauge of all the lines in the Argentine (except certain of the mountain lines of light traffic which could remain as narrow-gauge feeders, at least for some time)? The additional cost of conversion to the broad-gauge instead of the medium would not be so very great, in comparison with the whole cost in a scheme so large as this, and it would not be unreasonable to assume that, to obtain a result of such far-reaching benefit to the country, the Government of the Argentine, like that of Australia, would assume a large share of the burden.

Although there can be little room to question the statement that, for new lines in a country where construction is as light as it is in the Argentine, the additional extra cost for the wider gauge is so small as not to be worth considering, when compared with its great advantages over the narrow, the important question is the justification,

from a financial standpoint, of spending the amount necessary for the conversion of the existing lines, which, up to the present at least, have not shown such great deficiency in handling their business as would seem to warrant the expenditure of this sum in improvements.

It must not be forgotten, however, that, as pointed out on page 604 and in Appendix B, the character of the narrow-gauge lines is just now undergoing a radical change, from that of more or less small local lines, doing a small local business without competition, to that of a large trunk-line system, many of the lines of which are or will be competitive either with other broad-gauge lines or with river transportation, and they must either develop into an efficient transportation machine, capable of handling such business as may be offered at rates and in a manner which will compare favorably with those elsewhere, or be eventually crowded to the wall by transportation systems which can and will do this.

The underframes and draft rigging of the larger part of the rolling stock of the narrow-gauge lines is so light as to prevent its use in trains of any weight or length. The strengthening of these, or the provision of adequate strength in new equipment, will make the dead weight relatively large in proportion to the paying load, and in every way the narrow-gauge is forever limited in the matter of speed, comfort, stability, and economy of operation when compared with the standard-gauge.

If no great development or extension of the existing system of railroads were to be expected, it is doubtful if the expenditure necessary for conversion would be justified, but if the future development of the country is to be on the scale which a knowledge of it and a study of the general condition of the world's food market seem to indicate, it is believed that it can be.

The possibilities of double-tracking the existing narrow-gauge lines instead of widening the gauge, must, of course, be considered, especially as the cost of this on the lighter lines would be little, if any, more than the cost of conversion, and double-tracking could be carried out as required and without disturbing traffic in any way. It is doubtful, however, if a double-track narrow-gauge line has much greater efficiency or even capacity than an efficiently managed single-track line of standard-gauge (12 000 000 tons per mile of line per annum, or a total of 650 000 000 tons per annum, are handled on the Bald Eagle Branch, a single-track line of the Pennsylvania Railroad, 54 miles in length),

and then the cost of maintenance of double track is practically double that of single track. (See also page 580.) The cost of maintenance per ton-mile for any volume of traffic which might reasonably be expected in any part of the Argentine, except in the vicinity of the National Capital, would probably be almost, if not quite, twice as much for a double-track narrow-gauge as for a single-track wide-gauge, and the possibly somewhat greater ease of handling trains would be more than offset by the other operating economies possible on the wider gauge. In mountainous or even rough country, of course, the cost of double-tracking would far exceed the cost of changing the gauge, and it has been shown that the narrow-gauge offers very little advantage in decreased original first cost in rough country.

Looking at the question from the broad economic standpoint of the future development of the Argentine, it seems to the writer that the policy of continuing the construction of narrow-gauge lines is wrong, especially as it is believed that it can be shown that the additional cost of an efficient transportation machine, which the narrow-gauge is not, can be fully justified from the financial point of view, as well as from the point of view of its absolute necessity for the proper economic development of the country.

Cost of Unification for Argentine Railways Alone.—In calculating the cost, one must consider, not only the cost of changing the existing lines, but looking farther ahead, estimate the additional cost of the completed system as broad-gauge, over and above what it would cost to complete it as narrow-gauge. That is to say, supposing there are 10 000 km. of meter-gauge to be changed and 10 000 km. more to be built; the actual cost of changing might be $8 000 per km., the cost of building as 4 ft. 8½ in., possibly $1 000 or $2 000 per km. more than if built as meter-gauge, so that the added cost per kilometer for the whole of the completed system would be about $5 000 per km.

Taking the country only as far north as 22° South Latitude (the southern border of Bolivia), there is, north of the line of the existing railway from Sante Fé to Tucuman, a region comprising some 100 000 sq. miles (260 000 sq. km.) in the Argentine alone, and say, roughly, 25 000 sq. miles (65 000 sq. km.) more in Paraguay west of the Paraguay River at present served by only about 1 250 km. of railway. In other parts of the Argentine the length of railways in comparison with the area (for 1909) is approximately as shown in Table 23.

TABLE 23.

	Per 100 sq. miles.
Federal District	152.0 km. = 94.0 miles.
Province of Buenos Aires	7.2 " = 4.5 "
" " Cordoba	5.0 " = 3.1 "
" " Santa Fé	8.0 " = 5.0 "
" " Entre Rios	3.1 " = 2.4 "
Similar units for other areas are:*	
United States	14.1 " = 8.75 "
France	27.8 " = 17.22 "
Prussian-Hesse	40.0 " = 24.08 "
Great Britain	52.6 " = 32.65 "

* *Bulletin.* Bureau of Railway Economics.

It seems reasonable to assume that to develop this northern region there should be at least 5 km. of railway per 100 sq. miles, or a total of 6 250 km., of which there is now in existence some 1 250 km., leaving 5 000 km. yet to be built.

There is in existence at the present time in the whole country about 9 000 km. of narrow-gauge railway, of which 1 000 km. are strictly mountain lines of light traffic which need not be converted for some little time. In the next 20 years there will be required, say 4 000 km. of extensions to the existing lines, outside of this northern zone. So that, taken altogether, mountain lines and all, there will be 9 000 km. of the narrow-gauge to be converted and, say, 9 000 km. of new lines to be built.

To complete the unification of the gauge to 5 ft. 6 in., the standard-gauge lines must be included, of which there will be about 2 500 km. to be converted and about as much more new line required for extensions. The total additional cost of the final broad-gauge system, as compared with narrow-gauge, would then be:

Conversion of 9 000 km. of meter-gauge to broad, at $10 000 per km.	$90 000 000
Extra cost of building, say 9 000 km. of broad-gauge instead of meter, at $2 500.	22 500 000
Cost of changing 2 500 km. of medium-gauge to broad, at $6 500 per km.	16 250 000
Extra cost of building 2 500 km. of broad-gauge instead of medium, at $1 500.	375 000
	$129 125 000

That is looking ahead, say, 20 years, and not considering the existing broad-gauge lines. The average cost per kilometer of line then in existence as broad-gauge would have cost about $5 000 per km. more than if the existing narrow- and medium-gauges are perpetuated.

The interest on this, at 6%, is approximately $300 per km. per annum, so that, taking into consideration all the figures given in the previous discussions, and the several other undeniable advantages pointed out, it seems entirely reasonable to expect that, even with only a fair amount of business, the earning capacity of the broad- over the narrow-gauge would justify this expenditure, and, in addition to this, it is believed that there are many other reasons, particularly the narrow margin of safety on the narrow-gauge, the necessity of keeping the track in almost perfect condition in order to insure the possibility of even reasonable speeds and a fair amount of comfort, which warrant the expenditure.

The total expenditure indicated in the foregoing makes full allowance for the losses, if any, which might be due to the change of rolling stock. If, as has been proposed, the change was spread over, say, 10 or 12 years, quite a large proportion of the existing rolling stock would be used up during that period, and at the end of that time, in all probability, there would be direct connection with the narrow-gauge lines of the West Coast and the remainder of the rolling stock could be disposed of to roads in those countries, thus greatly minimizing this item; also, the difference in the value of the old rolling stock and the new would be much more than counterbalanced by the economies possible in the operation of the new rolling stock, all of standard types and of similar classes, and all selected in the light of the present knowledge of the requirements of the conditions to be met and the wide range of types now available to meet them.

The Best Gauge for South America.—The foregoing argument is based entirely on the point of view of the Argentine alone, without considering any of the adjoining countries or the necessities of international communications. If the whole of that part of South America referred to, that is, the part shown on the map, Plate I, is considered, however, the solution of the question as to which of the two wider gauges to adopt, 5 ft. 6 in. or 4 ft. 8½ in., is not quite so apparent.

The adoption of the 5 ft. 6-in. gauge in the Argentine leaves Paraguay and Uruguay with the medium (4 ft. 8½ in.), and it can hardly

be expected that either of these countries, more especially the latter, with some 2 290 km. of line, would consider a change from which it could expect no possible benefit. Brazil, because of the existence of a small quantity of 5 ft. 3-in. gauge, might possibly be inclined to favor the 5 ft. 6 in., but there is not enough of it really to influence the question either way. The 5 ft. 3-in. is neither one thing nor the other, and it would be practically as easy to change it to 4 ft. 8½-in. as to 5 ft. 6-in.; therefore, it seems far more likely that, if the change could be brought about, Brazil would prefer to change to 4 ft. 8½-in. as a standard, thus conforming with Uruguay and Paraguay and the existing lines in Entre Rios and Corrientes.

For the 19 000 km. of narrow-gauge lines now existing in Brazil it would cost about $40 000 000 or $50 000 000 less to convert them to standard-gauge than to 5 ft. 6 in. Looking toward the north, also, the lines of Peru are largely standard-gauge, even where they cross the highest passes of the Andes, and this really is the only logical gauge to adopt if an agreement could be effected between the different countries.

The conversion of the meter-gauge lines of the Argentine to standard 4 ft. 8½ in., and the adoption of that gauge for all new lines north of Santa Fé and Cordoba, and in the rest of the country, except for the legitimate extensions of the existing broad-gauge lines, would be a much less costly proceeding than that estimated above for their conversion to 5 ft. 6 in. It would provide an efficient transportation machine reaching from Buenos Aires to all parts of the country, and in harmony with the network already existing in Uruguay, Entre Rios, Corrientes, and Paraguay, and it might not be unreasonable to expect that, with this in view, Brazil would join in the movement, as there can be no question that such large areas as those under consideration cannot be efficiently developed by a transportation machine inferior to that which has achieved such wonderfully successful economic results in the United States, with which country this part of the world is most nearly comparable.

Making the estimate for the Argentine alone, on the basis of a change to 4 ft. 8½ in. instead of 5 ft. 6 in., and leaving out the existing 5 ft. 6-in. system, the cost of the completed system of standard-gauge roads would be as shown in Table 24.

TABLE 24.—Cost, in Gold Dollars.

Conversion of 9 000 km. of meter-gauge to 4 ft. 8½-in. at, say, $8 500 per km.	$76 500 000
Additional cost of building, say, 9 000 km. of 4 ft. 8½-in. instead of meter, at $2 000 per km.	18 000 000
Extra cost of building 2 500 km. of extensions in Entre Rios, Corrientes and Missiones	nil.
Cost of changing existing 2 500 km. in Entre Rios, Corrientes and Buenos Aires	nil.
Total	$94 500 000

That is, the standard-gauge system in existence at the end of 20 years would have cost about $4 000 per km. more than if the meter-gauge had been perpetuated. The interest on this at 6% would be about $240 per km. per annum, which it is believed could easily be saved by economy of operation, to say nothing of the necessity of having an adequate transportation machine.

Next, take the area south of 22° South Latitude and between the Atlantic Coast and a line drawn from Buenos Aires along the river to Santa Fé and passing through Tucuman and Salta to Sucre, but omitting the section north of São Paulo and Rio, already fairly well served by railways. There are in this area about 1 000 000 sq. miles, served by only about 12 200 km. of railroad or 1.22 km. for every 100 sq. miles of territory.

Of this area, the Province of Entre Rios is, perhaps, the best served at present, with about 3.9 km. of railway per 100 sq. miles, and it is seriously proposed to double this mileage within the next few years.

The railway mileage of the Argentine has increased three-fold in the 20-year period, 1890 to 1910, and it seems not unreasonable to expect the same rate of increase during the next 20 years in the area under consideration. It is true that the climatic conditions are not quite so favorable, but, on the other hand, the era of great expansion in North America, through the development of the country by new lines of railway, is now over, the world demand for pastoral and agricultural products is increasing, even the United States itself is just entering into the class of consumers, so that the development of this area seems inevitable, and will only be held back, if at all, by the lack of capital.

Assuming that there will be 25 000 km. built in this territory during the next 20 years, which will give a density of 3.7 km. per 100 sq. miles,

of this, probably, 5 000 km. will be of standard-gauge, in any event. Then the cost of a standard-gauge system throughout the whole area, including the cost of conversion of all the existing lines except those of broad-gauge of the Argentine, would be as shown in Table 25.

TABLE 25.

Cost of conversion of 28 000 km. of meter-gauge to standard, at $9 000	$252 000 000
Additional cost of building 20 000 km. of line, 4 ft. 8½-in. instead of meter, at, say, $2 500	50 000 000
Cost of conversion of 500 km. of 5 ft. 3-in. to 4 ft. 8½-in., at $1 000	500 000
4 800 km. in Uruguay, Entre Rios, Corrientes, and Paraguay not requiring change	nil.
5 000 km. of new line in Uruguay, etc., etc.	nil.
Total additional cost	$302 500 000

It will be noted that somewhat larger allowances for conversion, etc., are made for this whole system than for the Argentine alone.

The standard-gauge system in existence over this whole area at the end of 20 years, therefore, would cost about $5 000 per km. more than if the meter-gauge were perpetuated, this involving an annual interest charge of, say, $300 per km. The greater cost by including the lines of Brazil is due to the much greater present development of the meter-gauge system there, and also by additional allowances to cover the additional costs, as a great deal of the topography is much more accidented in Brazil than in the Argentine. On the other hand, no account has been taken of the vast areas in Brazil north of Latitude 20°, in much of which, especially in Eastern Brazil, there is likely to be considerable development by new lines, which, if built in the first place as standard-gauge, would reduce the average cost per kilometer of the whole system.

It seems to be not unreasonable to assume that, as many of the narrow-gauge lines will require stone ballast at a cost of from $1 500 to $2 500 per km., where the wider gauge could be operated just as well without, the completed system should be given some credit on this account, which might easily be as much as $1 000 per km. over the whole system, thus reducing the interest charge by $60 per km.

There is also the question of double-tracking many of the narrow-gauge lines, which would not be necessary if they were medium- or broad-gauge, and this would offset quite a little of the cost of conversion, though it is somewhat difficult to say just how much. Suppose, how-

ever, that 15% of the systems as narrow-gauge would have to be double-tracked and half of this, say 4 500 km., could be avoided by the change of gauge, there would be a saving of about $100 000 000 on this item alone, or one-third of the estimated additional cost of the whole system as standard-gauge.

It has been shown that, on the basis of the most conservative estimates, the saving in cost of operation made possible in only the one item of larger rolling stock, might easily be more than $300 per km. per annum, and as it is considered necessary even now to use 70- and 80-lb. rails on the narrow-gauge, this is not offset by the necessity of increasing the strength of the track to take care of the heavier rolling stock, as this weight of rail is ample to carry the ordinary standard-gauge equipment of fairly heavy types, on which these estimates are based.

It seems almost superfluous to point out the advantages of unification of the gauge. Besides the inconvenience of transfer and the actual cost of moving freight from one car to another, which has been variously estimated at from 5 to 10 cents per ton in India,* there is the actual damage to many classes of freight, such as fruit, etc. The transhipment of refrigerated products is impractical. Two cars are standing idle while any transhipment is being made, there are the unavoidable delays in yards waiting for the necessary cars of both gauges to be provided and shifted into position, and, above all, the loss in fluidity of rolling stock, which would be especially noticeable in both the Argentine and Brazil, where, for a few months during and after the harvest, there is an exceptional demand for rolling stock which could be used during the other seasons for hauling timber.

In the Argentine this question of transfer from one gauge to another has not become acute up to the present time, as most of the lines of each of the gauges reach terminal points on the water-front, to and from which most of their traffic flows. With the development of the country, the actual interlocking of the lines of the different gauges, and the present tendency to continue this mixing of the territories, this question, however, is bound to assume greater and greater importance, and the necessary transfers will be the cause of more and more inconvenience and delay.

---

* *Minutes of Proceedings*, Inst. C. E., "The Railway Gauges of India," by Sir Frederick Robert Upcott, Vol. CLXIV, p. 196.

It is true that the foregoing figures are based largely on assumptions, and may be varied widely in many individual cases, but it is believed by the writer that on the whole they represent a fair average, and at least tend to indicate that the adoption of 4 ft. 8½ in. as a standard, and the conversion of the existing narrow-gauge lines, can be justified on economic grounds and approximately so from the financial viewpoint.

It is hardly to be expected that these figures are definite enough to justify private capital in entering on an enterprise of such magnitude, but, taking into consideration the fact, which it is believed has been demonstrated, that the narrow-gauge is absolutely inadequate for the development of such large areas as those under consideration in the Argentine, Eastern Bolivia, Brazil, Paraguay, and Uruguay, to say nothing of the rest of South and Central America, it may not be unreasonable to expect such a measure of assistance from the Governments involved, which would be justified by the benefits they would derive from a system of railways of uniform gauge covering the whole area.

This argument, it will be seen, is based largely on the supposition of the continued and continuous development of these countries, which seems assured, provided the past policy of encouragement and appreciation of private capital is continued and the political situation remains as stable as it now seems to be. Without foreign capital, of course, this development will be tremendously retarded, to the benefit of competing countries like South Africa, Australia, and New Zealand.

It has been, and still is, the policy of the Governments of both Brazil and Argentine to build as State enterprises lines of railway to connect up or push the development of certain sections not sufficiently attractive at the time in themselves to private enterprise. Of course, the extent to which this can be carried out is more or less limited, as in all these newer countries there is a demand for more capital than is available; therefore, the Government lines, after a while, are sold or leased, and the capital thus acquired is used for further development elsewhere. It seems to the writer that, taking everything into consideration, such lines, if built to standard-gauge, would cost little if any more than have the meter-gauge lines, and there is no question at all but that they would be a far more valuable asset because of their undoubted greater economy in operation and their better salability

because of the wider market for any standard article than for one of inferior quality.

The 5 ft. 6-in. lines of the Argentine probably will not consider the change for the present, but, as they are fairly well confined to a limited area, it will do no harm to leave them as they are. They are efficient, and to attempt to include them in any scheme for unification of gauge would be to create a formidable opposition which it would be difficult to overcome. The adoption of 4 ft. 8½ in. as a standard for new lines, and the gradual change of the meter- and other narrow-gauge lines to the standard, however, should be established as the policy, if the requirements of the future are to be met.

It must be borne in mind that, as the distance from the seaboard increases, the necessity for cheap transportation becomes more and more important, and as this section of the world must depend for its future prosperity on its ability to compete successfully in the food markets of the world, cheap efficient transportation is a *sine qua non*. The United States has achieved results in this line which are far ahead of those obtained elsewhere, almost wholly by reason of the increase in train loading. It is quite certain that no narrow-gauge line can attain anywhere near the economic results obtained in the United States, and nothing which falls much short of this will solve the problem for the area under discussion, which only needs capital and adequate railroad transportation to show the most phenomenal development in the history of the world. This development, however, will be tremendously handicapped with anything less than the efficient, economical transport which can be furnished by standard-gauge railways.

In closing, the writer wishes to express his thanks to Mr. Percival Farquhar, President of the Argentine Railway Company, for permission to use much of the information contained in a report made to that company on this subject by the writer, to Mr. L. E. Young, of the Middletown Car Company, for data in regard to rolling stock, and to Mr. C. M. Muchnic, of the American Locomotive Company, for data in regard to locomotives and other information. It is believed that proper credit has been given in the text for quotations and assistance from engineering periodicals and other sources, but inasmuch as a fairly wide search of the literature of the subject has been made,

it is possible that some omissions of credit may have been made, if so, it is needless to say it has been unintentional.

Generally speaking, it is believed that the statistics given in the paper are substantially correct, and in any event such differences as there are do not affect the general argument, so far as the gauge question is concerned. As with all figures relating to railroads, there are often differences due to different methods of calculation or recording, and this is perhaps especially so in regard to South America. The writer, therefore, would esteem it a favor if those who may have more intimate knowledge of any facts will not hesitate to state them with a view to making the record as complete and accurate to date as may be.

APPENDIX A.

History, Experiences of Other Countries, Etc.

The following notes give briefly some account of the unification of the gauge of the railways in the United States and Mexico, the experience with lines of different gauges in India, Australia, etc., and Table 26 shows the length of lines of various gauges now in operation in the different countries of the world:*

TABLE 26.—Length of Railways of Various Gauges in Operation Throughout the World.

All Distances in Kilometers.

	Broad, more than 5 ft.	Medium, 4 ft. to 4 ft. 11 in.	Narrow, 3 ft. to 3 ft. 11 in.	Industrial, less than 3 ft.
Great Britain	4 959	40 017	909	104
Europe (Continent)	71 142	206 912	23 517	8 264
North America	.....	447 721	12 394	.....
Central America and West Indies	153	3 382	2 596	141
South America	18 852	6 663	37 115	3 094
Asia	43 781	11 650	41 299	2 618
Australasia	6 415	6 179	19 257	226
Africa	.....	5 275	27 843	4 039
Totals	145 302	727 799	164 930	18 486

Note.—The medium-gauge is nearly all 4 ft. 8½ in.
The narrow-gauge is nearly all meter or 3 ft. 6 in.

United States.—The following, prepared by Mr. George L. Fowler, of Messrs. Hildreth and Company, gives a brief statement of the history of the gauge discussion and its result in the United States.

"The narrow-gauge mania which possessed the railroad builders of the United States in the early Seventies was born of the bargain hunting desire to get something far below its real value. It was at the time very difficult if not impossible to raise money for the construction of new railroads of the standard-gauge. It was just after the civil war, and hard times were upon the country, yet in spite of this fact, the people over the whole land were clamoring for a more rapid development of the resources than was taking place, and this clamor was especially loud in its demand for an increase of railroad construction, but capital could not be obtained.

"It then occurred, to those who were most vitally interested in these constructions, that if cheaper roads could be built, the money for their construction might be obtained. They immediately, therefore, jumped to the conclusion that, because a gauge of 36 in. is only about three-fifths of 56 in., a road of that gauge could be built for a correspondingly lower price, and straightaway positive statements were made to that

* Compiled from "Universal Directory of Railway Officials," 1912.

effect, which were honestly accepted by a large number of men. It was assumed that, because the gauge was to be narrowed, all costs would be cut down in a corresponding degree. It was argued that because of the narrow-gauge, the cars would be made lighter than those which it had been found advisable to use on the broad-gauge, forgetful of the fact that equipment of the same, or even lesser, weight could and had been built and used on the standard-gauge lines, and had been found unsatisfactory.

"The whole case rested, apparently, so far as the United States was concerned, on the inability to raise money for ordinary railroad construction, and the narrow-gauge seemed to promise greater dividends on a given investment. It was characteristic of the whole discussion that the advocates of the narrow-gauge insisted throughout that their construction was the cheaper, and could not or would not see their opponents' side of the case, which was, that the narrow-gauge could not be built materially, if any, cheaper if the same facilities and capacity for the transportation of freight and passengers were to be afforded. They failed to see or acknowledge that a light locomotive and car could be built for a broad-gauge line.

"The physical disadvantages of the narrow-gauge, such as cramped storage and seating capacity, the greater instability of the rolling stock, and, above all, the chief drawback of the impossibility of interchanging cars with the standard lines, with the consequent extra cost and delays in transportation, were pointed out again and again, but in spite of all this the narrow-gauge construction went on for several years, and, until the money market eased, made a great headway.

"Meanwhile, the disadvantages of different gauges were making themselves manifest, and it was also being realized, with great rapidity, that heavy loads meant lesser costs than when light ones were hauled, so that between 1873 and 1885 there was a very rapid increase in the carrying capacity of the standard-gauge cars, rising as it did from 10 to 30 tons. With this rise the dead weight of freight cars dropped from a ratio of 1 lb. of dead weight to 1 lb. of paying load to ½ lb. of dead weight to 1 lb. of paying load.

"When the necessity of car interchange drove the broad-gauge lines to change to the standard (4 ft. 8½-in.) gauge, the narrow-gauge lines were left in a state of greater isolation than they had been at the outset of the movement.

"Finally, the recuperation after the panic of the Seventies made money more easily procurable for railroad construction, and the narrow-gauge roads, which had been built and equipped in the lightest and cheapest possible manner, found themselves doubly handicapped by their lack of facilities to do business, and by their isolation.

"The result of all of it was that, the furore past and the money market relieved, the narrow-gauge mania died a natural death, if a death from lack of substance can be called natural. The result then, of the forty years of practical experience that has elapsed since the battle of the gauges was precipitated in the early Seventies, has been to quite discredit the narrow-gauge system. It has been proven beyond all peradventure that the narrow-gauge railway cannot be operated so as to keep its ton-mile costs down to the figure obtained on the standard-gauge roads, and this has been the cause of its demise.

"Cars and locomotives of present capacities are impossible on a 3-ft. or 3 ft. 6-in. gauge, and time has shown that the contentions of the early opponents of the system were correct and that the narrow-gauge railroad cannot compete with the broad-gauge in capacity, facilities offered, or in cost of operation, when this cost is put upon the ton-mile basis."

The Denver and Rio Grande was the most important of the narrow-gauge lines changed to standard, and is interesting from the fact that it is a mountain line, of steep grades, very sharp curvature, and heavy work, crossing as it does the mountainous region of Colorado from Denver to Salt Lake City.

The change was started in 1886, during which year almost half the mileage (1 200 miles) was changed, the rest being done as the finances of the road permitted, and less than 6 months ago (September, 1912) it was decided to complete the last section, over Marshall Pass, a distance of 236 miles, the cost of which work, with the improvements in the line, is estimated to be about $2 000 000, or about $8 500 per mile.

It is of interest to note that on this line, which is now a link in a transcontinental route, and reaches an elevation of more than 10 000 ft., there are grades of 3.8% and curves of 150 ft. radius operated by heavy locomotives, and on which passenger trains of standard Pullman equipment are operated.

Many other lines in the United States were changed, but the largest mileage was in changing from 4 ft. 10-in., 4 ft. 11-in, and 5 ft. 0-in. to the standard 4 ft. 8½-in., this involving some 25 000 miles of various lines, mostly in the South. The total mileage of narrow-gauge changed to standard was probably about 5 000.

Mexico.—The principal railways in Mexico were built to standard gauge, 4 ft. 8½ in.; the gauge of the Mexican National, however—the original trunk line from the frontier of the United States to the City of Mexico, 1 200 miles in length—was made 3 ft. 0 in. Notwithstanding that it had a much shorter direct line to the United States, it was unable to compete with the Mexican Central and the International. In his Annual Report in 1889 the President of the Company said:

"Having been brought by experience to a realization of the inadequacy of a narrow-gauge road to develop a thoroughly satisfactory transportation service for a large volume of business * * * induced your management to take up some time ago the study of the practicability and desirability of changing the track to standard-gauge."

The line was changed to standard gauge between 1902 and 1904.

India.—The gauge of the Indian Railways has been the subject of almost endless discussion. Although nearly all who are familiar with the subject agree that a difference in the gauge of continental railways, or in countries as large as India, is unfortunate, all the discussion and the various reports of eminent engineers and transporta-

tion experts have led nowhere, and lines of both gauges are continuing to be built, apparently, however, only because the problem of conversion seems to be too big to handle. A few quotations from some of the discussions will show the attitude of some of the most prominent British engineers who have studied the subject. The matter was brought up officially for discussion by the Institution of Civil Engineers in 1906, the paper and discussion at that time occupying 135 pages of the *Minutes of Proceedings*, and, previous to that, at intervals as far back as 1873,* the following, at that time far-sighted, opinion was expressed:

"While the 3½-ft. gauge might answer for the carriage of heavy minerals in special districts, the general commerce of every populous country mainly consists of articles of low or medium specific gravity, such as food, clothing, fuel, etc., averaging about 80 cu. ft. per ton weight, for which the 5½-ft. gauge is in every respect most suitable as regards costs, stowage, safety, economy, the intricate elements of military defense, and the power of adopting single-track lines of railways for the accommodation of a large amount of traffic."

Mr. Thomas Robertson was appointed in 1903 as Special Commissioner by the British Government to report on the administration and working of Indian Railways, and in his report he pointed out the difficulties of working the two gauges, meter and broad, as follows:

"It will generally be admitted that a break of gauge is a drawback always, and that in certain eventualities it might prove extremely inconvenient. It necessitates a great deal of expense in the transshipment of traffic and a very much larger supply of rolling stock, since the unavoidable delays during the progress of transshipment absorb a large quantity of rolling stock of both gauges.

"The question is so full of difficulty and the evil is so far advanced that it is not easy to advise on it.

"Uniformity of gauge is bound to be demanded some day, and the longer a settlement of the policy to be pursued is deferred the greater will be the difficulty and expense of introducing it."

He discusses the relative merits of the two gauges, and favors the meter-gauge, largely because of the greater width of rolling stock in proportion to the width of the gauge. (This additional width, as is shown elsewhere, is not an unmixed blessing, as it is gained at the expense of safety and stability.) He concludes by advocating the unification of the gauge by the adoption of the medium-gauge, 4 ft. 8½-in.

In 1906 a paper was presented before the Institution of Civil Engineers of Great Britain by Sir Frederick Robert Upcott, Chairman of the Indian Railway Board, who pointed out the facts in regard to the gauge of Indian Railways without much comment. They were stated to be:

* And in *The Railroad Gazette*, November, 1872.

That the internal communications of the country were more important than any considerations of communication with other countries;

That the bulk of imports and exports was by sea;

Large internal trade;

The attempt to confine the narrow-gauge to a particular zone was useless, as these lines must find an outlet to the coast, and this created a great confusion at the ports by reason of difference in gauge;

The trouble and inconvenience of transshipment were considerable, and would by no means be measured by the cost of actual transfer of articles, but involved rolling stock standing idle, lack of fluidity of rolling stock, etc., etc.

Some of the discussions were, briefly, as follows:

Sir Guilford Molesworth had nothing to say against the meter-gauge as a gauge, but he did think the standard-gauge (5 ft. 6-in.) was better suited to the bulky agricultural traffic of India.

Sir George Bruce stated that when the discussion of this question came up in 1873 he estimated that the difference in cost of construction was very large, being based on the misconception that the width of gauge was the element which regulated the cost. It did nothing of the kind. With a coach of a given width, nothing was gained by putting the wheels closer together.

Mr. R. W. Egerton, commenting on a suggestion to change broad-gauge to narrow-, said:

"It would be economically unsound to substitute an inferior means of transportation for a superior one, at the same time increasing the capital cost * * *. The meter gauge, on account of the low limit of speed attainable, was an unsuitable gauge for large trunk-lines."

Mr. F. E. Robertson observed that most discussions on the gauge question had been vitiated by the implicit assumption that all the dimensions were geometrically similar, and, also, by the omission to remember that speed was a commodity which was sometimes worth money.

The difference in running speeds between the two gauges was not really known, for the broad-gauge (in India) was in this respect usually worked in such a leisurely way, that the meter-gauge had no difficulty in keeping fairly close to it.

Sir Frederick Robert Upcott, replying to a statement that high speed was not required in India, stated:

"Mr. * * * was incorrect in his views as to the need of rapid travelling in India. India, * * * was like every other country, and had progressive ideas of speed, comfort and safety, and the Railway Administrations would have to meet these needs for all classes."

Africa.—In connection with this same discussion of the gauge of the Indian Railways, there were the following expressions of opinion in regard to the gauge of the African Railways:

The General Manager of the Cape Railways wrote (1906):

"There has been considerable agitation on the subject of the laying of light railways during the last few years. I see no reason for changing the opinions I expressed in 1891 and 1892 on this subject, and I trust that Parliament will gravely consider the probable effect of the introduction of a narrower gauge than that of our own railways before authorizing such a breach of gauge. If the gauge originally adopted, 4′-8½″, had been continued instead of changing to 3′-6″ the journey from Capetown to Johannesburg would be performed in about half the present time. The effect of such saving of time in the passenger traffic would have been enormous, but if the present gauge is to be still further reduced, what will posterity think of the foresight, or want of foresight, in adopting a standard that limits the speed and carrying capacity of the trains? When the traffic is not expected to be heavy I see no reason why railways should not be constructed with less ballast than a standard line. When the traffic improves, the line could be better ballasted and prepared for quicker speeds and heavier loads."

C. O. Burge. "The line from the Zambesi river through to Cairo had been projected on a *miserable 3′-6″ gauge.* It would be found that the steamship companies, who were progressing faster than the railway projectors, would carry passengers from North to South Africa much more quickly by steamer than the railway could on a line of 3′-6″."

Japan.—Japan, after a most careful examination of the question, has decided to change the gauge of its railways to 4 ft. 8½ in. The 3 ft. 6-in. lines of that country were found to be entirely inadequate for the transport of troops and war material during the Russo-Japanese war, and, after a most careful consideration of the whole question, it has now been decided to make the change, the estimated cost of which is said to be about $150 000 000 for the 5 000 miles of line.

The South Manchurian Railway was originally 5 ft. 0-in. gauge and during the Russo-Japanese war was converted by the Japanese to 3 ft. 6 in., this being chosen because only rolling stock of that gauge was available. After operating it as a narrow-gauge road for 2 years, however, it was changed to 4 ft. 8½ in., corresponding with the gauge of the Korean Railways, and it has been stated that the Japanese have felt that they owed a debt of gratitude to the American engineers who built the first Korean railway and thus established a gauge which was of great service to them during the war, the 3 ft. 6-in. gauge which they were obliged to adopt temporarily for the South Manchurian Railway having been found entirely inadequate.

Australia.—The situation in Australia is described in the following quotation:*

* *Engineering Record*, September 28th, 1912.

"By some unfortunate misunderstanding, each now laying the blame on the other, New South Wales and Victoria started railways in the Fifties on different systems, the first on the standard, or 4 ft. 8½-in., and the latter on the 5 ft. 3-in. gauge, and, notwithstanding the advice of the engineers of the day, persisted, until now we have two great groups of over 3 500 miles each * * *. The slight difference of 6 in. stands much in the way of even the very inadequate remedy of a mixed gauge, owing to the difficulty and expenses connected with the construction and working of the switches and frogs in such a case.

"Subsequently, Queensland and Western Australia, attracted by the expected but exaggerated economies in the construction and working of narrow-gauge lines, which were too hastily assumed to be synonymous with light lines, adopted 3 ft. 6 in., and South Australia, after most of its main lines had been made to correspond with the width [5 ft. 6 in.] of those of its neighbor Victoria, introduced a local diversity by making its extensions and branches on the smaller, 3 ft. 6-in., basis.

"Unlike the United States and Canada who repented comparatively early in this matter, but at a cost of a large amount of money, Australia has done nothing but talk about it, and, owing to the enormous extension of each gauge in recent years, it is quite out of the question now to think of universal conversion, which might cost anything up to $60 000 000."

Finally, after the federation, it was decided to build a transcontinental line to unite the extreme easterly and westerly States of the Commonwealth, and, of course, the question of the most suitable gauge came to the front at once. After long debate and after calling to its aid the most expert advice, both engineering and other, that it was possible to obtain, the 4 ft. 8½ in. was adopted.

There still remained in abeyance the question of the gauges of the existing lines, but it has just recently been announced* that it has been decided to unify the gauges of all the lines, adopting 4 ft. 8½ in. as a standard and, in view of the general benefit of this to the whole country, the greater part of the burden of this change, estimated to cost about $175 000 000, will be borne by the Commonwealth as a whole.

As an example of the misleading statements often made in discussing the relative value of the gauge, the following is worthy of notice because it is so recent, and made by what one would suppose might be a competent authority.

In December, 1912, speaking at the Royal Colonial Institute in London, Sir Thomas Robinson, Agent General of Queensland, in describing the 3 ft. 6-in. railways of that part of Australia, made the statement that "Queensland had constructed 4 266 miles of railways of this gauge at practically half the cost of 3 807 miles of 4 ft. 8½-in. gauge in New South Wales." He omitted, however, to mention the fact that the total net earnings of the latter were more than double

* *Railway Age Gazette*, July 11th, 1913.

those of the former. He also stated that "in the working of the railway the comparatively light weight of the rolling stock gave it a great economic advantage over railways constructed on the wider gauge," yet said later, "Coming to rolling stock, the lighter engines and cars of the early days ran on lighter sections of rails, but the increased weight and power of the engines had necessitated the relaying of the permanent way with far heavier rails, * * * and the use of this heavier rail was steadily and surely extending from one end of the State to the other." He claimed that break of gauge has few disadvantages, yet stated that a new route has been laid out to the border of New South Wales on which "all the stations, tunnels, etc., had been built sufficiently wide so as to run the New South Wales trains (4 ft. 8½ in.) right through".

The consensus of all these opinions, from a wide range of territory and a very large number of prominent men, covering practically the whole of the railway systems in the English-speaking parts of the world, is decidedly against the adoption of lines of different gauges in the same country, and almost entirely in favor of the broad (4 ft. 8½ in. or 5 ft. 6 in.) as compared with the narrow (3 ft. to 3 ft. 6 in.).

APPENDIX B.

GENERAL DESCRIPTION OF THE TOPOGRAPHY, PHYSICAL CHARACTERISTICS AND BUSINESS CONDITIONS OF SOUTHERN SOUTH AMERICA; THE DEVELOPMENT AND PRESENT SITUATION OF ITS RAILWAYS.

In the following, the Argentine is referred to perhaps more particularly than any of the other countries, but this only because the writer is more intimately familiar with it, and the data he has available relate principally to the railways of that country. The conditions there, however, are quite generally similar to those elsewhere in this south temperate zone, and may be assumed to be applicable throughout most of this area and to its railways.

The northern limit of this section for convenience may be assumed to be about Lat. 20° S., that is to say, approximately equal to that of the southern coast of Cuba and the City of Mexico; its southern limit will be taken as the City of Bahia Blanca, Lat 39° S., which is equivalent to that of Baltimore. The latitudes of some of the more important cities may be compared with some of those of the northern hemisphere, as follows:

Rio de Janeiro,	Havana,
Santos and São Paulo,	Key West.
Antofogasta,	Key West.
Asuncion,	Cape Sable, Florida.
Valparaiso and Santiago, Chile,	Atlanta, Ga.
Buenos Aires and Montevideo,	Memphis, Los Angeles.
Bahia Blanca,	Baltimore, Denver.

It should not be inferred from this that there is no development in that part of the Argentine south of Bahia Blanca and Neuquen, and including Patogonia.

The railway development in this section, however, is not large, and is most likely to be dominated, as far as gauge is concerned, by that of the four important lines in the Province of Buenos Aires, which are 5 ft. 6 in.

The principal topographical features are the main range of the Andes and the River Parana, with its tributary the Paraguay, and the River Uruguay. The Andes occupy a comparatively narrow strip along the Pacific Coast, some 150 to 200 miles wide, broadening out at the northern end of Chile and in Bolivia. Between this range and the Parana and Paraguay Rivers is the vast almost level plain reaching from considerably south of Bahia Blanca to well up into Bolivia, which comprises nearly the whole of the Argentine. Uruguay, Paraguay, the two western provinces of the Argentine, Entre Rios and Corrientes, and the territory of Missiones, are considerably rolling to hilly. In Brazil the land rises abruptly from the coast line to elevations of 2 000

ft. and more, and then slopes generally toward the Rivers Uruguay and Paraguay, the intervening country being mostly rolling and in some parts rather broken and accidented.

In the Argentine there are few, if any, rivers of importance between the Parana and the Andes, the drainage from the easterly slopes of the latter, which is considerable, disappearing in the sandy soil before it has traversed the plain for any considerable distance. Toward the north, above the confluence of the Paraguay and Alto Parana, there are two important tributaries, the Bermejo and the Pilcomayo, the latter forming the northern boundary of the Argentine and dividing it from Paraguay and Bolivia. East of the Parana and Paraguay the country is generally well watered and the bridging of the rivers is an important item.

Lest the foregoing should convey the idea that much of the area of the Argentine is arid, it may be well to note further the peculiar geographical formation of this plain. The top covering of soil, which is of the richest character, and similar in appearance to that of the so-called "black waxey" belt of Northern Texas, at the Parana River and for some distance back from it, changes to a more friable and at times almost sandy loam farther back, and is underlaid by the so-called Pampean mud or "Tosca", a hard, indurated clay, almost shale. The water from the mountain finds its way between the top soil layer and the "Tosca" and between the successive layers of this latter, and is found almost everywhere by comparatively shallow borings. Nearly all of this is good or at least fair drinking water, but some is alkaline or slightly saline, and, therefore, bad for locomotive uses.

The railroad development of the Argentine, therefore, has gone ahead under the most favorable conditions, as far as facility of construction is concerned, and there has been practically no excuse at all for the adoption of the narrow-gauge. Some of the Government lines, notably that running from Tucuman north to La Quiaca, on the border of Bolivia, are in a mountainous country, but the proportion of the total is very small, and may be imagined when it is stated that more than 90% of the alignment is tangent.

Perhaps the most important physical characteristics which affect railway construction and operation are the scarcity of stone or gravel and the high cost of fuel. The coal that is used has to be imported from Europe. The scarcity of stone makes the question of ballast important, as the broad- and medium-gauge lines stand up much better with only earth ballast than do the narrow-gauge lines, and in comparing the quality of the track, the experience of the writer with the railways of the Argentine, leads him to think that it is almost fair to say that a fair stone-ballasted narrow-gauge track is no better than a good earth-ballasted wide-gauge.

The Argentine, as is perhaps well known, derives its wealth from

its pastoral and agricultural products. There are no manufactures of importance, as there is an almost entire lack of minerals and fuel, except wood. That part of the Argentine which, thus far, is developed most, as may be seen by the density of the railway lines, is in the Province of Buenos Aires and the southern parts of the Provinces of Cordoba and Santa Fé. This is an almost treeless plain, formerly devoted to little else than cattle raising, but now gradually being converted to agricultural uses, and the raising of the finer grades of cattle and horses, alfalfa replacing to a large extent the original native grasses. Wheat is cultivated mostly in the southern part of the Province of Buenos Aires and in the vicinity of Bahia Blanca, and exported largely from that port. Maize and linseed are the important crops farther north and in Entre Rios. The principal refrigerating and packing plants are on the Rio de la Plata and the River Parana between La Plata and Rosario. Quebracho comes from north of the City of Santa Fé, and nearly all the exports of it are from that port.

With the great valorization of the lands in this section, due to its agricultural development, the cattle industry is being pushed toward the north, and there seems to be little doubt that the world will soon have to look to this section for much of its meat supply, for the production of which there are vast areas of grass lands available in that part of the Argentine north of Santa Fé and reaching up into Bolivia and Paraguay, in many parts of this latter country, in Uruguay, and in Southern Brazil.

Up to the present time, nearly all the structural timber used in the Argentine has been brought from Europe and the United States, but it is now known that there are large forests of pine and cedar in the States of Parana and Sta. Catharina, in Brazil and in the Territory of Missiones. In Paraguay there are forests of important hardwoods which will now be made commercially available, as there has just been opened up through railway communication between Asuncion, through Corrientes and Entre Rios, to Buenos Aires, and a new line is under construction from Villa Rica on the Paraguay Central toward the east which will probably open up important timber industries and reach the forests where much of the yerba maté grows.

At Tucuman, and farther north between Salta and Embarcacion, there are important sugar industries, and the business of raising early fruits and vegetables for the markets of Buenos Aires, Rosario, Montevideo, etc., is already assuming considerable proportions. Mendoza and San Juan are the centers of quite important grape and wine industries, producing annually some 3 000 000 hectoliters (66 000 000 gal.) of wine, in addition to the grapes which are shipped in very large quantities during the season all over the country and even to Europe and the United States.

The great and important product of the so-called Gran Chaco, which

embraces in the Argentine practically all that territory in the triangle with Santa Fé as its apex and the Pilcomayo River as its base, is quebracho. These trees are not unlike scrub oak in appearance and are generally too twisted and crooked to be of use for structural timber. The wood is very hard and durable, and is used for railroad ties, fence posts, and telegraph poles, the trimmings, roots, etc., for firewood, and the smaller branches for charcoal. It is very rich in tannin, and the whole logs and the extract are shipped in large quantities to Germany for tanning purposes. The whole area of the triangle referred to, so far as known—and quite a little of it has not yet been explored—comprises large areas of forests with much quebracho interspersing the open spaces where the rich grasses provide excellent grazing for cattle. There are some parts which are alkaline, some swampy, some waterless, but, on the whole, it is believed that the greater part of it is useful especially as a cattle country and where maize, for feeding on the spot if not for export, linseed, cotton, tobacco, sugar cane, etc., can be grown. The quebracho forms the bulk of the freight for the Santa Fé Railway and the southerly end of the Government lines, and this is a product which demands rolling stock of large capacity for its transportation. It is of considerable importance, as it provides paying freight for new lines from the beginning, while the country is being developed pastorally and agriculturally.

Buenos Aires is by far the most important city in the Argentine. It is both the National Capital and the commercial center, its population, 1 300 000, is one-fifth of the total of the country; it receives 80% of the imports, and the exports passing through it are 60% of the total.

The principal other ports are Rosario, the second most important city, with a population of about 100 000, La Plata, the capital of the Province of Buenos Aires, Bahia Blanca, and Santa Fé. The imports which come to these places are mostly coal and lumber, but cereals are exported from all of them as well as from quite a number of smaller places along the rivers where ocean-going steamers can lie alongside the bank and load, being served by short spurs of the railroads tapping the districts adjoining. The Port of Buenos Aires is served by a Port Railway of 5 ft. 6-in. gauge operated by the Government, with a strong feeling against admitting any other gauge. The Port of Bahia Blanca has been developed by the railroads, is served by three broad-gauge railways over their own lines, and has had a very rapid development. The Ports at La Plata, Rosario, and Santa Fé, have mixed gauge (5 ft. 6 in. and meter), the first and last operated by the Government, and Rosario by a French Corporation under a concession for its exploitation.

Most of the merchandise is imported through Buenos Aires and distributed from that city throughout the country, the imports passing through this port being about 6 500 000 tons for 1910, and the exports about 2 000 000 tons. A small proportion of the imports, about

25% of the total tonnage, and consisting principally of lumber and coal, comes directly to Rosario, and in much lesser quantities to Bahia Blanca, La Plata, and Santa Fé, with a scattering to some of the smaller ports.

The cereals are exported principally from Rosario and Buenos Aires in about equal quantities, with Bahia Blanca the next in importance, and then a scattering from a considerable number of smaller ports along the Parana and a few on the Uruguay. The cereals flow naturally to the nearest seaport, ocean-going steamers reaching as far as the City of Santa Fé on the River Parana and Concepcion del Uruguay on the Uruguay River.

Cattle (live) are shipped from all over the country (see Fig. 5) for distribution to the packing plants on the river between La Plata and Rosario. The cattle from Corrientes and parts of Entre Rios go to the plants along the Uruguay River which take, principally, the inferior grades for extracts, dried beef, etc. There is also a considerable movement of cattle from one section to another for growing, fattening, etc., and for shipment to the west coast by driving across the mountains in summer.

There is good passenger business on nearly all lines, sleeping and dining cars being in general use.

The conspicuous feature of the freight traffic, of course, is the cereals. There is a heavy demand for cars during the shipping season, February to June, and in this period quite a large proportion of cars are returned empty, this unbalancing of the traffic being noticeable on nearly all the lines.

In Brazil, of course, the most important products are coffee and rubber, the former coming from that section of the country to the north of São Paulo and Rio. This territory, as will be seen by Plate I. is served by a fairly dense network of railways which, however, are of two different gauges.

The following table shows the quantities of the principal items of export for 1906. The cotton, sugar, cocoa, and tobacco, are mostly from Pernambuco and Bahia to the northeast of Rio; rubber, of course, comes from the Amazon, and the other products from the States to the south of Rio. The quantities are long tons.

Sugar	85 000	tons.
Cotton and cotton seed	35 000	"
Rubber	62 200	"
Cocoa	25 000	"
Tobacco	23 600	"
Coffee	840 000	"
Maté	57 800	"
Flour and bran	31 500	"
Hides	27 500	"

FIG. 5.

The principal products of the three southerly States of Brazil, namely: Parana, Sta. Catharina, and Rio Grande do Sul, are timber, some agricultural products, and the yerba maté, of which latter thousands of tons are gathered annually and shipped to points all over the southern part of Brazil, Uruguay, and the Argentine. The development of this section will probably be largely along agricultural and pastoral lines, together with the exploitation of the forests of timber in the western sections.

Uruguay is likely to remain an almost entirely pastoral country, with some agriculture, and, as it is served by a fairly efficient system of standard-gauge railways which shows a healthy normal growth, it does not call for much detailed consideration in the present discussion, except perhaps to call attention again to the fact that this section, Uruguay, the Provinces of Entre Rios and Corrientes, and above them Paraguay, forming a connected area as shown by the map, is served exclusively by medium-gauge lines.

Chile, although one of the most important countries in South America, has little influence on the present discussion, inasmuch as it is cut off from the vast areas to the east by the high cordillera of the Andes. Its railway development was originally that of a series of lines from the mountains to the coast, and more or less perpendicular to the latter, although in recent years, under the influence partly of the scheme for a Pan-American railroad and partly for the development of its internal communications by a means independent of the coastwise steamers, it has put under construction the so-called "Longitudinal" railway, traversing the narrow strip along the foot-hills through the length of the country. The existing and proposed international connections of the Chilian Railroads are noted later.

Bolivia has been little developed, except for the exploitation of its mineral resources, and what development there is has been principally in the high mountain plateau to the south of La Paz. This has been reached from the south by the 2 ft. 6-in. line from Antofogasta, which, at its highest point (on a branch) reaches an elevation of 15 809 ft., the highest railway in the world, and from the north by the Southern Peruvian line (4 ft. 8½-in. gauge) from Mollendo and Cuzco. Within the past year the Arica-La Paz line (meter-gauge) has been completed, giving Bolivia an additional outlet to the Pacific, but all three of these lines have very steep gradients, and summit elevations of 15 000 ft. or more, so that they have only a limited capacity. It is expected that eventually there will be a considerable development of the eastern side of Bolivia, on the lower slopes of the mountains, and on the vast well-watered plains between them and the State of Matto Grosso in Brazil, and the outlet from this section of the country must inevitably be toward the Atlantic seaboard, either south through the Argentine, which if longer is, though much easier country, eastward through Para-

guay and Brazil to Rio de Janeiro and Santos, or northward through the Valley of the Amazon.

All this vast section seems to be entering on an era of development fostered by an ever-increasing tide of emigration from Europe, comparable only to that of the United States, and when it is considered—to take only one example—that the commerce of the City of Buenos Aires is growing at a rate at which it will probably be doubled in less than 10 years (the commerce of New York is doubled in about 20 years) it will be seen that the question of the policy of the future development of the railways is one of great importance. Figs. 6 and 7 show the increase in trade, exports, and imports, and the areas under cultivation for the three most important cereals.

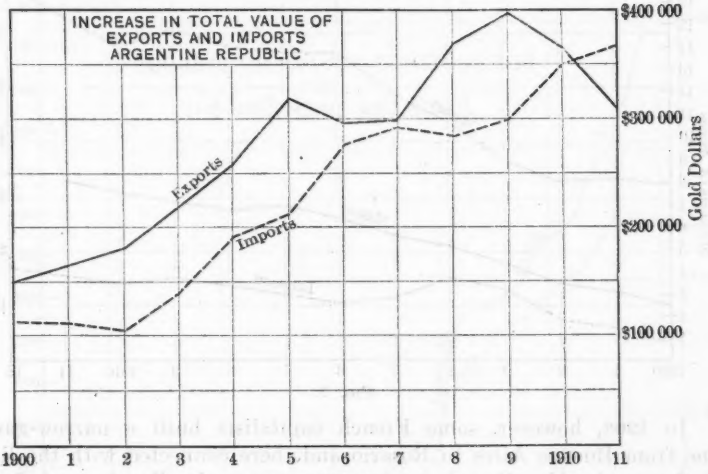

FIG. 6.

Immigration in the Argentine has increased from about 100 000 per annum in 1903 to 300 000 in 1910, by far the larger proportion being from Italy, Spain, and France, in the order named. The progress of railway construction is shown by Fig. 8. As will be noted, it has been rapid and steady, except for the setback following the crisis of 1890.

The latest official statistics of the Argentine Railways published are those for 1909, but Table 27, showing the length in operation, capitalization, earnings, etc., of the various lines for the year ending December 31st, 1912, is approximately correct.

The four broad-gauge lines are by far the most important. They have been built, and are controlled, by British interests. These lines radiate from the City of Buenos Aires, and have been most influential in the development of the country. They are so strongly intrenched

that they are a most important factor to be kept carefully in mind in any consideration of the question of gauge, as it seems entirely improbable that their owners and managers can be shown that there would be any benefit in changing.

The narrow-gauge lines of the Argentine have been principally developed in the section north of Rosario and Cordoba, and, until within comparatively recent times, partook more of the character of small local lines than of a connected system of trunk lines, none of them having reached the National Capital.

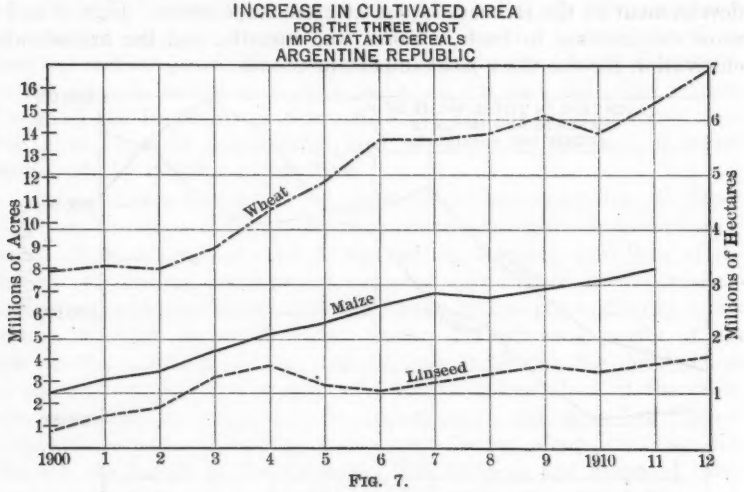

FIG. 7.

In 1908, however, some French capitalists built a narrow-gauge line from Buenos Aires to Rosario and there connected with the lines of the much older French company operating the Province of Santa Fé Railway reaching to Resistencia at the confluence of the Paraguay and Alto Parana, and connecting at Santa Fé with the Government lines through Tucuman to La Quiaca on the Bolivian border.

The Central Cordoba system, which had been formed by uniting some three or four small lines between Rosario, Cordoba, and Tucuman, with headquarters at Cordoba, decided about this same time to build an extension to Buenos Aires from Rosario, and thus connect its system with the National Capital, this line being opened to public service only about a year ago, and the headquarters of the system transferred to Buenos Aires. The Central Cordoba connects with the other part of the Government system, the Argentino del Norte, and also with the Central Norte at Tucuman.

The narrow-gauge lines are thus divided now into three groups: The French lines radiating in three directions from Buenos Aires and

extending north along the Parana up to Resistencia; the Central Cordoba starting from Buenos Aires and passing through Rosario and Cordoba to Tucuman, and the Government lines reaching all the capitals of the northern and Andean provinces and scattered along the foot-hills of the mountains between San Juan and Bolivia, connecting at Cordoba and Santa Fé with the other lines and thus having through communication with Buenos Aires.

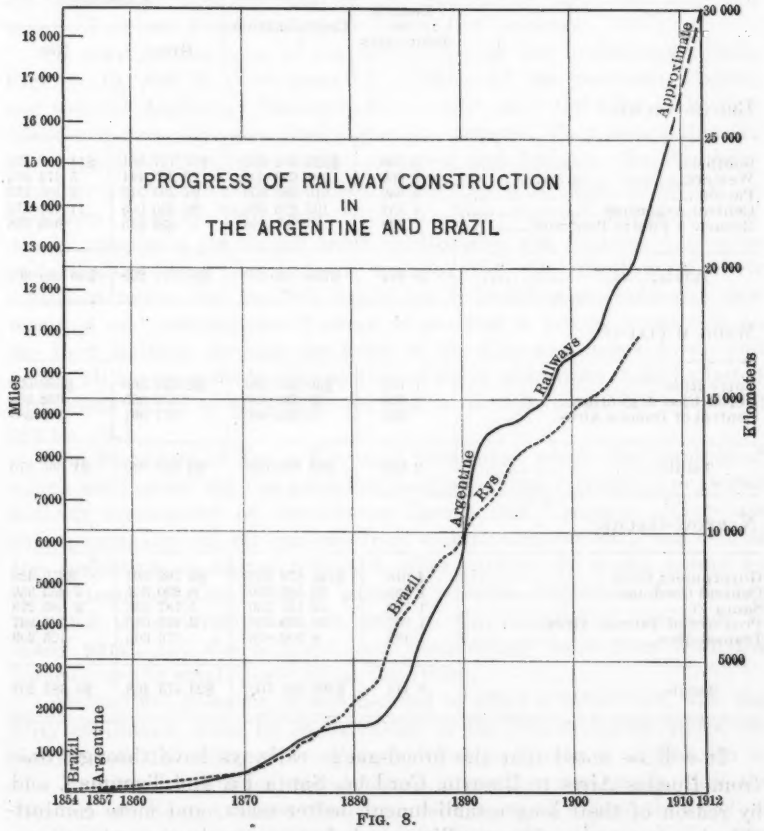

FIG. 8.

These conditions on the narrow-gauge lines must be kept well in mind, as they are just now emerging from a status as more or less isolated lines, doing a small local business, to that of a more or less coherent group of systems of trunk lines connecting the National Capital with the northern section of the country, and reaching nearly all the provincial capitals. As local lines doing a small business, the gauge in itself mattered little, but now, with the greatly increased

business that is coming to them, and the growing necessity of running through express trains at fairly good speeds, they find themselves handicapped by reason of this very increase in business, because they have not the facilities for doing it properly.

Totals	9 114	$282 831 700	$23 473 468	$5 383 204

It will be noted that the broad-gauge railways have through lines from Buenos Aires to Rosario, Cordoba, Santa Fé, and Tucuman, and, by reason of their long establishment, better track, and more comfortable, because easier-riding, rolling stock, have up to the present monopolized the through passenger business to and from these points. In order, therefore, to get their share of this business, the narrow-gauge lines will be forced to make considerable improvements in their service, starting with the physical condition of their roadbed and track, and working up and even then, of course, can never compete on even terms.

It is often pointed out, in discussing the gauge, that these narrow-gauge lines have done very well, that their capitalization is small and, therefore, there is no reason to change, but, as will be shown later, it seems to the writer that they must look forward to the growth of the country and be prepared to meet it by modern economic means of transport or be crowded out. By the time they have provided adequate terminal facilities in the large cities, their capital expenditures will not be so much less than that of the broad-gauge lines, and they can never, of course, handle the same amount of business.

To convey some idea of the importance of the broad-gauge lines, Figs. 9, 10, and 11 show parts of the lines of the Southern, Pacific, and Central Argentine Railways, where they enter the City of Buenos Aires over expensive steel and masonry viaducts. They have extensive and expensive terminals, both passenger and freight; the Southern has four tracks for some distance out of the city. Fig. 12 shows the Southern Railway Passenger Station. The Central Argentine has nearly completed its second track to Rosario; the Central Argentine and Western have plans under way for the electrification of their suburban zones; the Central Argentine is building an extensive new terminal and station; the Western is building a tunnel connection to the Port Railway through the heart of the City of Buenos Aires, and nearly all have a considerable portion of their main lines stone-ballasted with stone at $2 to $3 (gold) per cu. m. f. o. b. cars ($1.50 to $2.50 per cu. yd.).

The Provinces of Entre Rios and Corrientes, within the confines of which are located the two principal medium-gauge railways, are almost entirely surrounded by the Rivers Parana and Uruguay. They are thus practically cut off entirely from communication with the rest of the Argentine, or indeed with any other part of the world, except by water transportation. Their isolated position, therefore, has rather retarded their development, in spite of the richness of the lands in many parts, and the railways have been merely local lines from the interior to the small ports along the rivers.

About 1906, however, it was decided to effect a connection with the City of Buenos Aires by an extension of the line to Ibicuy and a car ferry across the delta of the Parana River to Zarate, a small town in the Province of Buenos Aires. Here connection was made with the Central of Buenos Aires Railway, then a rural steam tramway of medium-gauge, over which running rights were obtained into the City of Buenos Aires, though at a point a fairly long distance out from the center. This through line was opened to public service only about 4 years ago.

At about the same time, also, the Central Railroad of Paraguay, which at that time was a broad-gauge line running from Asuncion, the capital of that country, to Villa Rica in the interior, was changed

to medium-gauge and extended to Encarnacion, opposite Posadas in Corrientes, and another car ferry established there, so that by these two car ferries, through train service between the City of Buenos Aires and Asuncion, through the Provinces of Entre Rios and Corrientes is now possible, thus putting all this section in close touch with Buenos Aires and the outside world.

It will be seen, therefore, that the whole railroad situation in the Argentine has undergone a radical change during the past 5 years or so. Previous to that time, the four large broad-gauge systems controlled by British interests, which in many respects were identical, dominated almost exclusively the transportation of the country, and the lines of other gauges were of little importance. Now the medium-gauge lines are not only linked together, but are all (except the Central of Buenos Aires) controlled by mutually friendly interests with a through route some 900 miles long from Buenos Aires to Asuncion. The narrow-gauge lines are linked up into not more than three systems, all of which are working together in harmony and may come under a single control. They reach the northern section of the country and the one in which the great development of the next 20 years is to take place. The question is, shall this development be by means of a system of narrow-gauge lines, can such a system offer adequate transportation facilities, and can it offer competition to the broad-gauge lines, should they decide to extend their lines into this section, and with river transportation on the Parana?

There is also to be considered the question of international connections, and the present and rapidly increasing interest in South America, both by Europe and North America, makes this important. To the writer the idea of a Pan-American Railroad as a continuous trunk line for the transportation of through freight and passengers from the United States and Canada to the extreme south, has always seemed almost chimerical. The variation in gauges, as will be seen, is an important obstacle, and such a line can never hope to compete for long-distance transportation through a tropical climate and across the vast and lengthy stretches of the most rugged mountains in the world, with the facilities offered by ocean steamers.

It is easy, of course, to foresee that at some time in the future, which seems now not a little distant, the various lines of railway will be linked together, and that there will be continuous connections. This, however, will not be, at least in the writer's estimation, until there is a local demand and local business sufficient to warrant the construction of the various constituent parts. It is also entirely probable that such a line will be useful and will be used for international communications, between any two or more countries within reasonable limits, and for this reason uniformity of gauge should be advocated throughout the continent and through the Central American zone,

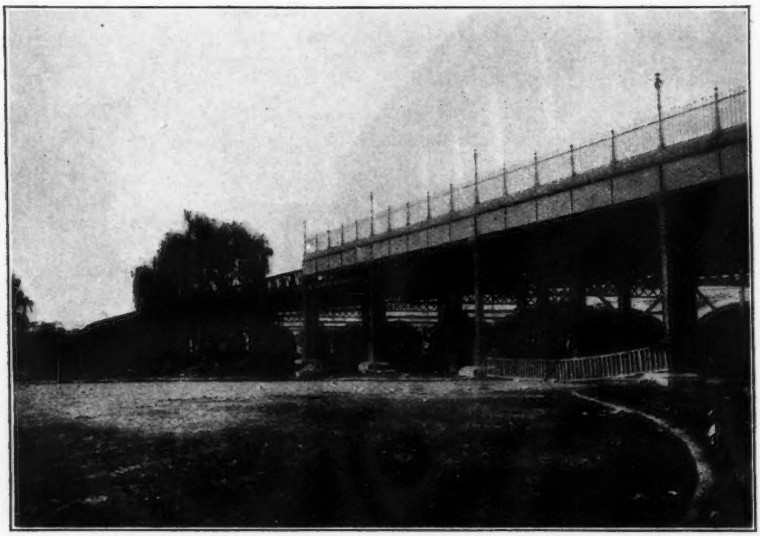

FIG. 9.—OLD STEEL VIADUCT, CENTRAL ARGENTINE RAILWAY, ENTERING BUENOS AIRES.

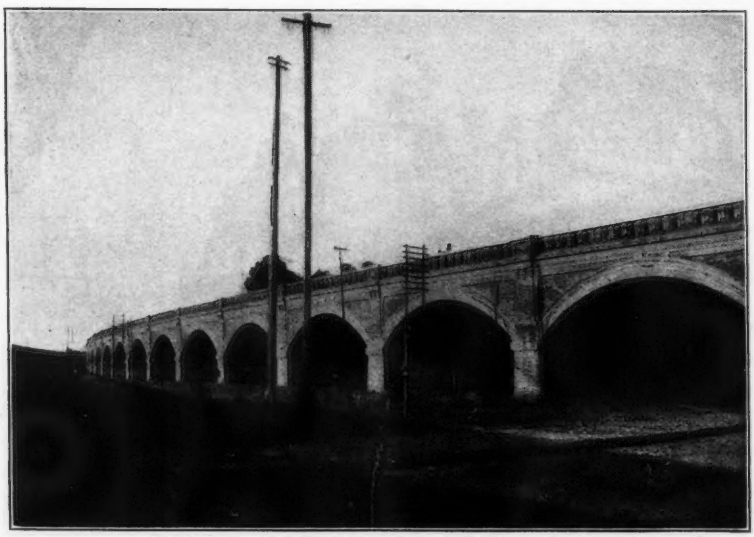

FIG. 10.—MASONRY VIADUCT, PACIFIC RAILWAY, ENTERING BUENOS AIRES.

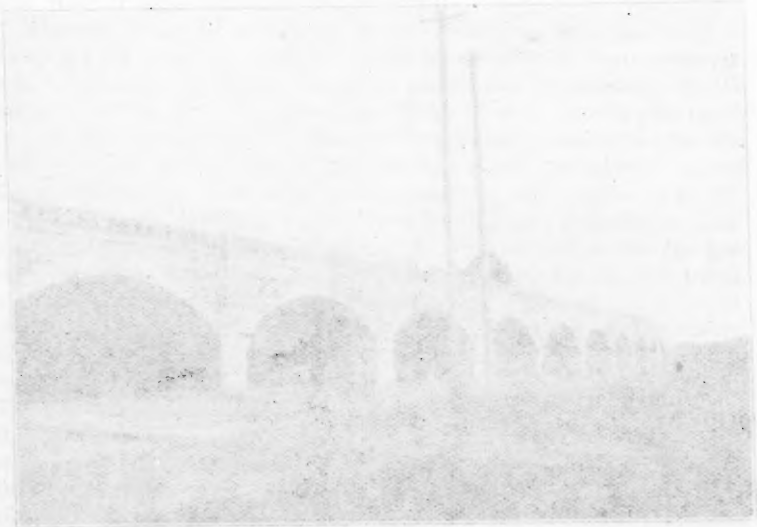

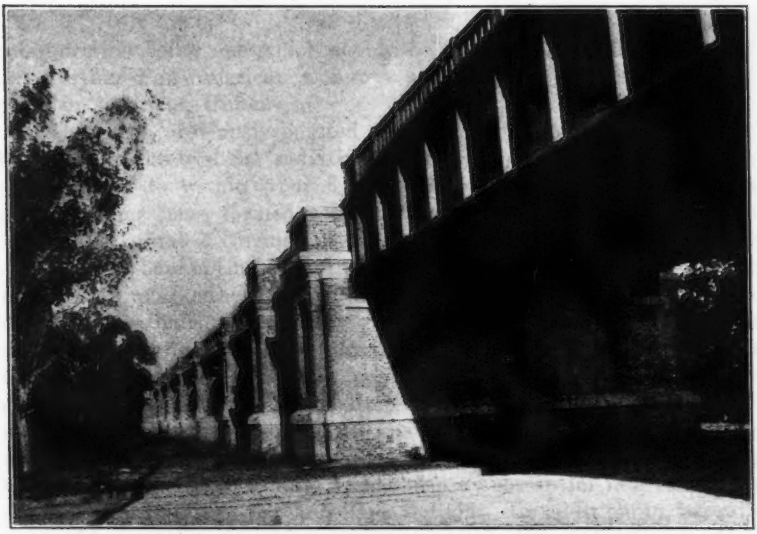

FIG. 11.—STEEL BRIDGE AND MASONRY VIADUCT, CENTRAL ARGENTINE RAILWAY, ENTERING BUENOS AIRES.

FIG. 12.—SOUTHERN RAILWAY PASSENGER TERMINAL STATION, BUENOS AIRES.

this question being one which should be most energetically pressed at any further Pan-American Congresses and by the representatives of the Pan-American Union.

It has been previously pointed out how, in the Argentine, the four big broad-gauge systems radiating from Buenos Aires dominated the situation up to within 5 or 6 years ago, and how, since then, the other systems have formed coherent groups with connections to the National Capital. During the same period, also, an international syndicate of bankers has acquired control of the railway lines in the three States of Southern Brazil, and a substantial interest in those in the southerly half of the State of São Paulo. This same syndicate also has operating control over three lines in the Argentine, the Rosario á Puerto Belgrano, 5 ft. 6-in. gauge, the Central Cordoba, meter-gauge, and the Entre Rios, medium-gauge, it has established a community of interest with the North East Argentine Railway, which connects the Entre Rios Railway with the Paraguay Central Railway, which latter it also controls. It has also a substantial interest in the Antofogasta Railway, in Chile and Bolivia. In addition to its railways, this syndicate is taking great interest in the exploration, exploitation, and development of the countries served by its lines and those beyond into which they may be extended.

One of the lines controlled by these interests has already been pushed across the State of São Paulo, crossing the Alto Parana nearly 1 500 miles above its mouth, and, eventually, without doubt, will be pushed ahead through the State of Matto Grosso into Eastern Bolivia and to Sucre on the headwaters of the Amazon. Another line is projected along the boundary line between the States of Parana and Sta. Catharina, following the Valley of the Iguazu to its confluence with the Alto Parana, crossing the latter at a point some 500 miles below that of the line into Matto Grosso, just referred to, and connecting with the line now under construction eastward from Villa Rica on the Paraguay Central. This will give a through route from Rio, São Paulo, and all points in Southern Brazil to Asuncion, the capital of Paraguay, though there will be a break of gauge at the border. From Asuncion this line will probably be extended northwestward between the Pilcomayo and Paraguay Rivers toward Sucre.

There is another east and west line still farther south in Brazil from Porto Alegre to Uruguayana, a point on the River Uruguay opposite Paso de los Libres on the North East Argentine Railway, where connection can be made either to Santa Fé or Resistencia on the west side of the Parana, and from these latter places to all points in the northern section of the Argentine and to Bolivia. This latter route at present involves more or less delay, steamer transportation across the two rivers, and two breaks of gauge, but eventually this will be developed into a through route.

There is already through rail connection between Rio and Montevideo, with breaks of gauge, however, at São Paulo and at the border of Uruguay and Brazil. At least two schemes have been proposed for a short through line from Colonia, a point in Uruguay opposite Buenos Aires, to Rio, over which passengers can be carried in express trains at reasonably fast speeds, and thus shorten the length of the sea trip between the Argentine and Europe, and the time between Buenos Aires and Rio by nearly half. This, if it is ever realized, means a standard-gauge line through Southern Brazil, as the Uruguayan gauge is fixed and it would be out of the question to get the necessary degree of speed and comfort on any lesser gauge to compete with the fast, luxurious ocean steamers in which the trip can now be made and which are being improved every day. Perhaps present conditions hardly warrant the construction of this line as yet, but that it is a development of the not far distant future is hardly open to question.

There is, as is perhaps well known, one line which now crosses the Andes, giving direct rail connection between Buenos Aires and Valparaiso. This, however, involves a change at the break of gauge at Mendoza in the Argentine and at Los Andes in Chile, the Buenos Aires and Pacific is 5 ft. 6-in. gauge, the Transandine in the Argentine and Chile is meter-gauge, and the Chilean lines with which it connects are 5 ft. 6 in. Another connection is proposed in the south by the extension of the Southern Railway's (5 ft. 6 in.) line from Neuquen, and there is a proposal (which, however, it does not seem will be carried through in the immediate future) to build a line from Salta in the Argentine to Mejillones in Chile. Farthern north, the Antofogasta Railway has been building an extension southeastward from Uyuni toward Tupiza, and probably before long it will be connected with the lines of the Argentine Government (meter-gauge) at La Quiaca.

Turning now to the Argentine: The area west and south of Bahia Blanca, it seems, must inevitably be developed by the Southern and Western Railways, that is, by the 5 ft. 6-in. gauge, and the country north of Santa Fé and Cordoba is the part in which may be expected the most important developments of the future which will be of interest to this discussion.

The line of the Central Cordoba Railway from Cordoba to Tucuman, and the Government line from Tucuman by Salta to Embarcacion may be taken as marking the dividing line between the mountains and the vast Argentine plain. Between Santa Fé and Tucuman there are two lines, the more southerly being the Central Argentine broad-gauge, and the more northerly the Central Norte, meter-gauge, operated by the Government. It is the area north of this latter line and east of the line from Tucuman to Embarcacion, and known generally as the Gran Chaco, in which the development of new territory by new

lines will probably be most active in the Argentine. The topography of this region is almost as blank as the space shown on the map, and its character does not change for at least some distance north of the Pilcomayo in Paraguay and Bolivia. The distance from Santa Fé to the northerly border of this region is about 750 miles, and from Asuncion to Tucuman about 550 miles, and it is probably safe to assume that railways may be built at a minimum cost and in practically straight lines over almost any portion of it.

Santa Fé is a port at present available at lowest river stages for ocean-going steamers drawing 18 ft. of water, and this depth will probably be increased in the near future. It seems to the writer improbable that there will be a port for ocean-going steamers established north of this point, so that the commerce of this vast region must come to Santa Fé. It is true that there may be some competition by way of the rivers, but experience elsewhere has shown that this will not be a serious matter for properly equipped railroads, though it might be for lines any less efficient than those designed in the light of the best present knowledge of the art. This area must be served by railroads of some sort, they must be efficient if they are to pay and be able to compete with water transport.

The Argentine Government has commenced the development of this region by lines running more or less westward from points on the Parana River at Resistencia and Formosa, apparently with the idea of bringing the products from the interior to the river and thence by fluvial transportation to the coast, the merchandise and supplies returning the same way. This, the writer believes to be fundamentally wrong, and that this area might better be developed by a series of north and south lines from Santa Fé and points on the existing lines between Santa Fé and Tucuman, which will reach up into the north beyond the Pilcomayo and bring all this vast region in touch with Buenos Aires. Here it may perhaps be well to refer again to the importance of the City of Buenos Aires as a distributing point for all merchandise, its dominating influence over the whole country as the seat of the national government, and the absolute importance of proper and adequate means of transportation to reach it from all parts of the country.

A certain number of east and west lines between Brazil and the north, along the lines already being developed, and as already indicated, will be necessary of course for the interchange of products and for communication between the large populations which will, in all probability, occupy this area before another quarter of a century has passed, but the line of least resistance to and from the southern part of eastern Bolivia, western Paraguay, and the Chaco is by the most direct north and south routes between this section and Buenos Aires.

The exact details of the lines along which the future development of this area may proceed, however, are not of particular importance in this discussion. The outline of the general scheme which has been presented will at least tend to show its close resemblance to that of the United States during the time our great West was being opened up to agricultural developments. Knowing as we do the important role played by the railroads in this era, it seems obvious that a system of transporation less efficient than our own in moving bulk freight long distances at low cost would handicap the development of the great area in the Southern Hemisphere.

THE POSSIBILITIES IN BRIDGE CONSTRUCTION BY THE USE OF HIGH-ALLOY STEELS.

By J. A. L. Waddell, M. Am. Soc. C. E.

To be Presented April 15th, 1914.

Summary.

As bridges of exceedingly long span are needed these days in a number of places, it has become necessary to use alloys of high elastic limit and great ultimate strength, in order to lessen materially the dead load to be carried. Up to the present time, nothing more satisfactory or effective than nickel steel has been found; and even that alloy has not been developed to the limit of its practical possibilities. This is due solely to a reluctance on the part of manufacturers of bridge metal to take any special pains in its production.

The time has come to discover some alloy of steel (or some other metal) of great strength, which, in every detail, will be suitable for undergoing the manipulations required of bridge material during the various processes of fabrication.

The objects of this paper are:

First.—To show, for the different span lengths, what the weights of metal per linear foot of bridge would be, in both simple-truss and cantilever structures, when using metals of various elastic limits, ranging from that of ordinary carbon steel up to 100 000 lb. per sq. in.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

Second.—To indicate the extreme practicable limits of span length for cantilever bridges constructed for the greater part of such materials.

Third.—To demonstrate the comparative economics of finished bridges involved in using metals of the several assumed elastic limits, for all reasonable excess costs of metal per pound, delivered at site, as compared with carbon steel structures.

In the diagrams which form a part of the paper, Figs. 5 and 6 show the weights of metal per linear foot of structure for double-track railway bridges of simple-span and cantilever construction, beginning with short spans and extending to the limits of utility. Directions are given in the text for finding the weights of metal per foot for bridges having any number of tracks and for those designed with other live loads than those adopted in the preparation of the paper. From these diagrams and from the text it will be seen that the possible limits of main span length for cantilever bridges vary from some 2 000 ft. for carbon-steel structures to about 3 500 ft. for those built of metal having an elastic limit of 100 000 lb. per sq. in.

Figs. 10 to 21, inclusive, are diagrams showing the costs of metal erected per linear foot of bridge, in both simple spans and cantilevers, for the different elastic limits assumed. There is a curve for each excess pound price of metal work, delivered at site, above that of carbon steel; and these excesses vary by ½ cent. per lb., and extend always slightly beyond the greatest increase that need be considered. On each diagram there is shown, by a line heavier than the others, the cost of erected metal per foot of structure for carbon-steel bridges under the conditions assumed, so as to afford a means of instantaneous comparison of costs between any all-carbon-steel bridge and the corresponding structure built chiefly of the metal to which the diagram pertains.

Figs. 22 and 23 show the comparative economics of all the alloy steels (or other metals) considered, under the assumption that their pound prices for material delivered at the bridge site are the same.

In his paper on "Nickel Steel for Bridges",* the writer showed the results in bridge construction obtainable by the use of nickel steel, and although the limits of attainment indicated therein have not yet

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 101.

been reached by American bridge builders, because the metal manufacturers are not willing to guarantee an elastic limit of 60 000 lb. per sq. in. for that alloy, nevertheless, since its publication, a number of important structures have been built of nickel steel, and the manufacturers have indicated to the engineers a willingness to increase their set elastic limit of 50 000 lb., provided they be satisfactorily compensated. The obstacle in the way of adopting a 60 000-lb. elastic limit is the fact that there is no market for the rejected material. The writer is of the opinion, however, that, after a little experience, the manufacturers would have no more trouble in furnishing the alloy with an elastic limit of 60 000 lb. than in furnishing ordinary carbon steel with an elastic limit of 35 000 lb. The best practicable solution of the difficulty is an agreement by the purchaser to pay the manufacturer a fair compensation for his loss by rejections. The writer's reason for thinking that no great trouble will be encountered in manufacturing nickel steel with a minimum elastic limit of 60 000 lb. is that the inspection sheets for the Free Bridge over the Mississippi River at St. Louis, engineered by the late Alfred P. Boller and Henry W. Hodge, Members, Am. Soc. C. E., seldom show an elastic limit materially less than that, although the requirement fixed by arrangement with the manufacturers was only 50 000 lb.

It is the writer's intention, on the first opportunity that presents itself to him for building a bridge of very long span, to construct it of mixed nickel and carbon steels, placing the alloy wherever it can be used to advantage, and arranging, if possible, with the manufacturers for a minimum elastic limit of 60 000 lb., so as to show actually what can be accomplished by adopting nickel steel of that strength, and complying with the specifications given in the before-mentioned paper on "Nickel Steel for Bridges".

A condition which at present militates seriously against the use of nickel steel in bridge building is that the manufacturers ask for it an additional price of some 2 cents per lb., as compared with ordinary carbon steel, although but little more than one-half of that would be a sufficient excess price. This, undoubtedly, is because structural steel manufacturers naturally object to fundamental innovations, preferring to follow lines of least resistance; but, as a number of very long steel spans are contemplated for the near future, they will certainly be forced sooner or later into using high-alloy steels.

Again, it has been stated authoritatively to the writer by Mr. T. L. Willson, the eminent Canadian authority on thermo-chemistry, that ferro-nickel, containing 10% of nickel and nearly 90% of iron, can be furnished with a good profit at 2 cents per lb. for adding to the molten carbon steel in the manufacture of nickel steel, and that no trouble would be involved in burning out all the impurities contained in the said ferro-nickel. This would make the nickel content in the alloy cost about 10 cents per lb. instead of 30 cents, as assumed in the before-mentioned paper. The economics involved by such use of ferro-nickel will be treated hereinafter.

During a recent conversation with two of the largest European producers of nickel, the writer was told that it would be practicable for them to furnish pure nickel in large quantities for the purpose of manufacturing bridge material and to sell this pure nickel at about 20 cents per lb.; but they dropped the hint that they were in no hurry to do so, as the demand for that metal to-day is in excess of the supply, and the main obstacle in the way of large production is likely to be a scarcity of satisfactory nickel ores.

When in France in 1909, the writer's attention was called to the fact that certain metal manufacturers in that country were making, in melts of 5 tons and less, a purified carbon steel, for which rather astonishing claims, in regard to great ultimate strength, high elastic limit, and general suitability for the manufacture of bridges, were made; and on his investigating the matter by both interview and correspondence, he was convinced that these claims might, at least partly, be justified by performance. Thereupon, having some spare time, he prepared an economic study of the possibilities for utilizing such purified steel in bridges, using in his calculations French units, prices, and other conditions, and published the results in French,* under the title, *"Étude Économique de l'Emploi de l'Acier au Carbone à Grande Résistance, pour la Construction des Ponts."*

The excess cost of this purified steel, as compared with ordinary carbon bridge steel, was claimed to be a little less than 1 cent per lb. for the manufactured bridges; and the investigation showed the economics of its use in bridge building for the mean and the extreme conditions of the French metal market, and for a number of elastic limits varying

* *Le Génie Civil*, August 7th, 1909.

from 30 to 45 kg. per sq. mm., the value for French carbon bridge steel being 24 and that for the writer's specified nickel steel 42.5 kg. per sq. mm. The result of the study indicated that there was no advantage for the 30-kg. elastic limit; none for short spans but a small one for long spans with a 35-kg. elastic limit; a decided saving for all cases with a 40-kg. limit; and a wonderful economy for the 45-kg. limit, the highest elastic limit claimed by any of the French manufacturers.

The writer had hoped that that paper would give an impetus in France (and perhaps elsewhere also) to the manufacture of bridges of purified steel; but, up to the present time, he has not heard of any such development. It is either that the claims of the manufacturers have not been justified by performance, or that the same conditions of inertia and *laisser aller* exist in Europe, in respect to innovations in the manufacture of new bridge metal, as govern in America in relation to the adoption of nickel steel for bridges.

As the future development of America will necessitate the building of many very long-span bridges, it is almost a necessity that there be found an alloy of steel of great strength, high elastic limit, workable under all necessary manipulations in the shops, and of moderate cost. Such an alloy is not going to be discovered by accident, but only by a lengthy and exhaustive series of experiments, laid out systematically in advance, and modified from time to time as knowledge of the subject is accumulated. These experiments should be performed where small melts of steel are readily procurable, and where the experimenter will not be unduly delayed by the metal manufacturers. These conditions are found in France—for there one can procure single ton melts, and possibly smaller ones, if necessary. Arrangements could be made with the mills for rolling into plates and shapes the metal from the various melts without delay; and the experimenter could have at his disposal, not only a first-class testing machine, but also a bridge shop, where all the usual manipulations of the metal might be made. By experimenting at first on different kinds of alloy materials and later on mixtures thereof, one eventually should discover some satisfactory combination that would afford a suitable material of great strength at comparatively moderate cost. The more elaborate and thorough the experiments, the greater the probability of discovering a truly suitable steel of exceedingly high resistance at a reasonable expenditure for production and manufacture.

Such a series of experiments would be expensive, costing fully $100 000, and possibly twice that amount; but the saving in cost on one big bridge alone might easily exceed the entire expenditure. The money required for such experiments could not be obtained from bridge manufacturers, because it is not to their interest to inaugurate changes; but it might be secured from some millionaire philanthropist or from a group of capitalists who contemplate the construction of some great steel bridge.

To show the possibilities for long-span bridge construction by the use of such superior alloys of steel, and the economics thereof, is the object of this paper.

The basis of the following investigation is a mass of diagrammed and tabulated data concerning weights of metal in simple-span and cantilever bridges of carbon steel, up to a limit of 600-ft. spans for the former and 1 800-ft. main openings for the latter, accumulated by the writer and his firm during the last quarter of a century, and the weights of nickel-steel bridges and of mixed nickel-steel and carbon-steel bridges computed by the writer in the preparation of his before-mentioned paper on "Nickel Steel for Bridges". Because the said diagrammed weights of metal per linear foot of span in simple-truss bridges are limited to lengths of 600 ft. it has been found necessary, in preparing this paper, to extend them to 1 000 ft. by making actual calculations of stresses, sections, and weights of metal for several long spans, using the various kinds of steel assumed. From these recorded and specially computed weights, and by the succeeding formulas of reduction and extension, have been prepared the various diagrams of weights of metal per linear foot of span contained in this paper.

Many preliminary and tentative diagrams of curves were constructed, but, for considerations of space and cost, they are not included herein. These individual diagrams, prepared for each class of steel and each type of bridge, divided the weights into those for "Floor System"; "Lateral System"; "Trusses"; and "On Piers"; but in the selected diagrams only the total weights of metal per linear foot of span for a combination of all the parts of the structures are recorded, as these quantities constitute the results sought, and to be used in the succeeding economic investigation. Near the end of this paper, however, are given some tables from which can be found the approximate values of weights of metal per linear foot of span for "Floor

Systems"; "Lateral Systems"; and "On Piers"; and from these and the diagrams, Figs. 5 and 6, can be computed the weights for "Trusses".

The weights given for bridges of carbon steel are based on the standard specifications for designing contained in the writer's "De Pontibus". They are quite accurate up to the before-mentioned limits of 1 000 ft. for simple spans and 1 800 ft. for the main openings of cantilever bridges. Beyond these limits (shown on the diagrams by dotted lines) they are to a certain extent conjectural, although, in all probability, not far from correct, because of the thorough consideration which has been given to all factors influencing their values.

The weights for steel having an elastic limit of 60 000 lb. per sq. in. are those obtained for the diagrams of the paper on "Nickel Steel for Bridges", and are based on the specifications contained in that paper. They are quite accurate up to the before-mentioned limits of 1 000 ft. for simple-truss spans and 1 800 ft. for the main openings of cantilever bridges; and a comparison of the curves for cantilevers of openings from 1 200 to 2 600 ft., shown in Fig. 71 of the writer's Nickel Steel paper with those of Fig. 6 of this paper indicates, in general, an excellent agreement. In the former the curves beyond 1 800-ft. openings were determined by an assumed regularity of continuity, as explained in that paper, and in the latter they were computed by the use of Equation 19 of this paper.

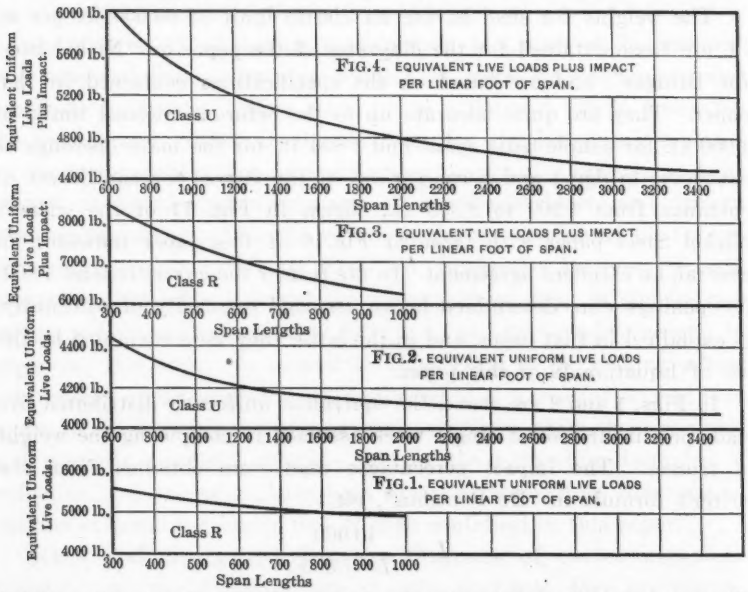
In Figs. 1 and 2 are shown the equivalent uniformly distributed live loads per linear foot of single track assumed in computing the weight of trusses. The impact percentages used were obtained from the writer's formula in "De Pontibus", *viz.:*

$$I = \frac{40\,000}{L + 500},$$

where I is the percentage of impact and L is the length, in feet, of the portion of the bridge which must be covered by the moving load in order to obtain the maximum stress on the member under consideration. Although it is true that the writer has evolved a more accurate formula than this, based on some lately made experiments on impact in railway bridges from moving loads, he has decided to adhere to the old formula so as not to necessitate the changing of the weight curves on which this investigation is primarily founded. Figs. 3 and 4 give a combination of the equivalent uniform live loads and the impacts therefrom. The loads obtained from these curves added to the dead loads

make the total loads per linear foot on the bridges, from which total loads the load ratios of reduction are found.

The following are the formulas of reduction used in passing from known weights of metal per linear foot of span in carbon-steel bridges to the corresponding weights in alloy-steel bridges. An observation of the nomenclature will show that the unaccented capital letters severally represent weights of metal per linear foot of span in carbon-steel bridges (or otherwise known weights of bridges of any kind of steel), and the accented capital letters, the corresponding weights for alloy-steel bridges (or otherwise the corresponding unknown weights of



bridges of some other kind of steel), also that the small letters severally represent linear dimensions of structures, the main exceptions being that capital R is used for reactions and small r for ratios.

Floor System.—

Let F = weight of metal per linear foot of span in the "Floor System" of carbon-steel bridges.

L = ditto for "Lateral System".

T = ditto for "Trusses".

P = ditto for "On Piers", including anchorage material in the case of cantilever bridges.

A certain portion of the weight of the floor system will vary inversely with the elastic limit of the steel, and the remainder will be invariable.

Let V = the variable portion,
and I = the invariable portion.

Then $F = V + I$ .....(1)

Let F' = the weight of metal per linear foot of span in the floor system of alloy-steel bridges,
and r (greater than unity) = the ratio of elastic limits of alloy steel and carbon steel,

Then $F' = I + \frac{V}{r}$ .....(2)

In heavy, double-track bridges, and especially those of long span, I will be approximately 0.35 F, and V approximately 0.65 F, hence

$$F' = 0.35\ F + \frac{0.65\ F}{r} = F\left(0.35 + \frac{0.65}{r}\right) \text{ .....(3)}$$

In dealing with spans of greater length than any of those yet actually computed, it must not be forgotten that the increasing width of structure will augment the weight of the floor-beams and, consequently, the weight of metal per linear foot of span for the floor system. In case of double-track bridges, an economy can be effected by widening the cantilever arms and the anchor arms uniformly from ends to supporting pier; but it is probable that motives of policy would lead the projectors to construct exceedingly long spans so as to carry more than two tracks.

Lateral System.—

Let l_1 = length of span at which it pays to begin to use high steel for the laterals beyond the ends of l_1, it being assumed that the weight of laterals is uniform over the entire length, l_1, or, in other words, that minimum sections are used therein throughout;

R_1 = wind reaction at end of l_1;

R = wind reaction at end of span l;

r_w = ratio (greater than unity) of R and R_1;

L_1 = weight of carbon steel per linear foot for lateral system over the length, l_1;

L'_2 = weight of mixed carbon and alloy steels per linear foot of span at end of span, l:

$$\text{Then } L'_2 = L_1 \left(0.3 + 0.7 \frac{r_w}{r}\right).$$

Let L'_a = average weight of metal per linear foot for entire span, l,

$$\text{Then } L'_a = \frac{1}{l} \left\{ L_1 \, l_1 + \frac{L'_2 + L_1}{2} (l - l_1) \right\} \ldots\ldots\ldots (4)$$

Should L'_2 figure less than L_1, it shows that near the ends of the span minimum sections of the high steel must be used and that L'_a will equal L_1.

In passing beyond the limits of actually figured spans, when computing the weights of metal in lateral systems, it must be remembered that, as just explained for the floor system, the weight per foot is increased, not only because of the greater span length but also because of the greater span width. As a rule, it may be stated that, for any very long span (the length thereof remaining constant), the effect of increasing the width between central planes of trusses $n\%$ is to increase the weight of metal in the lateral system about $\frac{n}{2}$ per cent.

Trusses.—In respect to the weight, T, of metal per linear foot of span for trusses of carbon steel, the following equation may be used:

$$T = K + T_1 + C_c + C_w \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

where K is the portion of the total truss weight per linear foot which is independent of the quality of the metal and of the stresses; T_1 is that of the main portions of the tension members and of their details that are directly affected by the stresses; C_c is that of the main portions of the compression chords and inclined end posts and their details that are directly affected by the stresses; and C_w is that of the main portions of the compression web members.

From experience in designing large bridges it may be stated that, as an average,

$$K = 0.2T$$
$$T_1 = 0.3T$$
$$C_c = 0.3T$$
$$C_w = 0.2T$$

Both T_1 and C_c (and consequently their sum) will vary inversely with the elastic limit of the metal; but C_w, on account of the influence of the ratio of strut length to least radius of gyration, will not vary in that ratio. As an approximation it may be assumed that, in passing from any grade of steel to a higher grade, if, as before, r (greater than unity) is the ratio of the elastic limits of the two metals,

$$C'_w = \frac{1}{2} C_w \left(1 + \frac{1}{r}\right) \quad \ldots\ldots (6)$$

$$\text{and } C'_c = \frac{C_c}{r} \quad \ldots\ldots (7)$$

Substituting these values in Equation 5, we have

$$T' = K + \frac{1}{r}\left(T_1 + C_c\right) + \frac{1}{2} C_w \left(1 + \frac{1}{r}\right) \quad \ldots\ldots (8)$$

Substituting the values of K, T_1, C_c, and C_w in terms of T as previously given, we have

$$T' = T \left(0.3 + \frac{0.7}{r}\right) \quad \ldots\ldots (9)$$

In finding the new truss weight per linear foot for a higher steel, after computing it (as just indicated) for the direct effect of increased elastic limit, it must be corrected for the indirect effect, which is the changed total load per linear foot for trusses. This correction is made thus:

Find the sum of the live load, impact load, and dead load per linear foot of span, for the known truss weight, T, and then determine approximately the corresponding sum (on the basis of an assumed final value of T'_f) for the new truss weight. Let the ratio of these sums (less than unity) be r_1, then

$$T'_f = T' \ (0.3 + 0.7\ r_1) \quad \ldots\ldots (10)$$

where T'_f is the final value of the truss weight. Combining Equations 9 and 10 gives

$$T'_f = T \left(0.3 + \frac{0.7}{r}\right) (0.3 + 0.7\ r_1) \quad \ldots\ldots (11)$$

If the computed value of T'_f does not agree quite closely with its value adopted in determining the trial dead load, a new dead load is to be assumed, and the calculations are to be made afresh. The second attempt, in all probability, will give a sufficiently accurate agreement.

On Piers.—To find the new value, P', from the old value of P, the span length being unchanged, the following approximately correct equation may be used:

$$P' = P\left(0.6 + 0.4\,\frac{r_1}{r}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

where r and r_1, respectively, are the ratios previously indicated for elastic limits and total loads per linear foot of span.

In extending a curve of simple truss weights of metal per linear foot of span beyond the limits of accurate computations, the following formulas may either be used directly or as a check, the character of the steel, of course, being unchanged. Assume first that the live and the dead loads per linear foot of span remain constant, and consider the effect only of longer spans and greater truss depths. Dealing first with the chords, some 85% of their weights of metal per linear foot of span vary directly as the moments of the total loads and inversely as the truss depths; but the moments vary as the squares of the span lengths, and the stresses are inversely as the truss depths. Again, the truss depths within short limits may, without serious error, be taken to vary directly as the span lengths. Such being the case, 85% of the weights per foot of the chords will vary directly as the span lengths, or

$$C' = 0.15\,C + 0.85\,C\,\frac{l'}{l} = C\left(0.15 + 0.85\,\frac{l'}{l}\right) \ldots (13)$$

where C is the chord weight per foot for the shorter span, l, and C' is the corresponding weight for the longer span, l'.

Let W and W' be, respectively, the weights of metal per linear foot of span in the webs of the two spans. About 75% of these will vary directly as the averages of all the live-load and dead-load shears on the spans, and these average shears vary almost directly as the span lengths. Again, the said 75% of W and W' will vary directly as the truss depths, and, therefore, as previously assumed, once more directly as the span lengths.

Combining these ratios will give the equation:

$$W' = 0.25\,W + 0.75\,W\left(\frac{l'}{l}\right)^2 = W\left\{0.25 + 0.75\left(\frac{l'}{l}\right)^2\right\} \ldots (14)$$

but $T = C + W$,

and $T' = C' + W' = C\left(0.15 + 0.85\,\frac{l'}{l}\right) + W\left\{0.25 + 0.75\left(\frac{l'}{l}\right)^2\right\}$.(15)

It is well known that in trusses with parallel chords and of economic depths the weight of the chords is equal to the weight of the web; but, in trusses with polygonal chords and having center depths less than the theoretically economic ones, as do those of all long-span bridges, the weight of the chords is much greater than that of the web. As a general average, we may assume that $C = 0.6\ T$, and $W = 0.4\ T$, hence

$$T' = 0.6\ T\left(0.15 + 0.85\frac{l'}{l}\right) + 0.4\ T\left\{0.25 + 0.75\left(\frac{l'}{l}\right)^2\right\}$$

$$= T\left\{0.19 + 0.51\frac{l'}{l} + 0.3\left(\frac{l'}{l}\right)^2\right\} \quad \ldots\ldots\ldots\ldots (16)$$

This value of T' is based on the incorrect assumption that the total loads per linear foot of span are the same for both spans under consideration, hence it requires a further modification, as follows:

$$T'_f = T'\ (0.2 + 0.8\ r_1) \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

where T'_f is the final value of the weight of truss metal per linear foot of the longer span, and r_1 (in this case greater than unity) is the ratio of the total loads per linear foot.

Combining Equations 16 and 17, we have

$$T'_f = T\left\{0.19 + 0.51\frac{l'}{l} + 0.3\left(\frac{l'}{l}\right)^2\right\}(0.2 + 0.8\ r_1) \ldots\ldots (18)$$

A test of this formula, on carefully computed curves of truss weights for simple spans of nickel steel from 600 to 1 000 ft. in length, shows that slightly undue prominence has been given to the invariable portion of the weights, and that the following modification of the formula will give more accurate results:

$$T'_f = T\left\{0.15 + 0.55\frac{l'}{l} + 0.3\left(\frac{l'}{l}\right)^2\right\}(0.15 + 0.85\ r_1) \ldots (19)$$

This last formula, when tested on the truss weights of simple spans from 700 to 1 000 ft. in length for an elastic limit of 90 000 lb., gave exceedingly close results; hence it is proper to adopt it as the equation for extension of all truss weights for simple spans, and, inferentially, for those of cantilever bridges; in fact, it has been tested on some of the actually computed truss weights of cantilever bridges and found to give excellent agreement.

Attention is called to the semi-rational, semi-empirical character of these reduction and extension formulas. They are, in general, the result of long personal experience in the quick computation of metal

weights for bridges; but they have been modified slightly, as hereinbefore indicated, to agree with certain checks that have been made in this investigation. As far as practicable, the formulas of Equations 11 and 19 were used for checking each other; and the results of such checks were always satisfactory. For instance, if a curve of truss weights for one class of steel were used as a basis for finding, by Equation 11, the corresponding curve for another class of steel, the latter curve would be checked by starting from any desired point (generally where the weights of actually computed bridges cease) and passing, by using Equation 19, from one span length to another, 100 or 200 ft. greater, and continuing in this manner to the superior end of the curve.

Fig. 5 gives the total weights of metal per linear foot of span in simple-truss bridges with Class R live load. A glance at it shows the great saving in weight of metal obtained by using any of the alloy steels in preference to carbon steel. The difference is most apparent between the weights for $E = 50\,000$ lb. (the nickel steel that the metal manufacturers are willing to furnish) and those for $E = 60\,000$ lb. (the nickel steel used by the writer in his series of experiments some 8 or 10 years ago, and which alloy could be readily produced by the manufacturers through the expenditure of a little extra care and without any greater expense worth mentioning). The gradual reduction in the saving of metal with the increase of elastic limit is strikingly noticeable; and the conclusion may be drawn that, unless the extremely high-alloy steels can be obtained with only moderate increase in cost, there will be no economy in using them in simple-span bridges.

Fig. 6 gives the average total weights of metal per linear foot of span for cantilever structures having main openings of various lengths. The type of these bridges is the most common one (denominated "Type A" in "Nickel Steel for Bridges"), the live loads used being Classes R and S for the floor system and Class U for the trusses, as given in "De Pontibus." The proportional dimensions of this typical, through, cantilever bridge are as follows:

A main span, l, having a suspended span of three-eighths of l, and two cantilever arms each five-sixteenths of l in length, also two anchor arms of the same length as the cantilever arms. Any reasonable variation from these proportions would not change materially the average weight of metal per linear foot of span, as given by the curves

Lengths of Main Spans

FIG. 6.

on Fig. 6. In this figure the superiority of the alloy steels over the carbon steel is just as clear as it was in the case of the diagram for simple spans, but the advantage of using very high steels is evidently greater.

If (as can be seen by the diagram to be logical) it be assumed that a limit of 36 000 lb. of metal per linear foot of span is as high as it is either economical or practicable to go in the building of double-track, railway, cantilever bridges, the corresponding limiting lengths of main openings will be approximately as follows:

For carbon steel	.....	2 030 ft.
" $E =$ 50 000 lb. steel	.....	2 340 "
" $E =$ 60 000 " "	.....	2 590 "
" $E =$ 70 000 " "	.....	2 780 "
" $E =$ 80 000 " "	.....	2 910 "
" $E =$ 90 000 " "	.....	3 030 "
" $E =$ 100 000 " "	.....	3 140 "

The assumption of a limit of 36 000 lb. of metal per linear foot of span as a maximum, means that, for carbon steel, there would be required at this limit 4.35 lb. of metal to support each pound of live load that is carried (exclusive of impact allowance); and that for the alloy steels of the various elastic limits the corresponding figures are 4.37, 4.39, 4.40, 4.41, and 4.42 lb., respectively, the average of which is about 4.4 lb. From the appearance of the curves at their superior ends one may draw the conclusion that, in the case of the very high-alloy steels, the limit of weight of metal per linear foot of span can legitimately be raised beyond the said 36 000 lb. The more nearly these curves approach the vertical the more uneconomical would it be to extend the limit beyond the 36 000 lb. per lin. ft. For instance, it is plainly evident that there is no advantage in carrying the carbon-steel bridges beyond the limit of 2 000 ft. for main opening, but it is otherwise for the $E =$ 100 000-lb. curve. Continuing this curve by deflections, it is found that the weight would reach 46 000 lb. per lin. ft. for a span of 3 400 ft.; and that the inclination from the vertical at that point is greater than that for the carbon-steel curve at its limit of 36 000 lb. with a main opening of 2 030 ft. Perhaps, therefore, in the case of the highest steel herein considered, it would be more correct to assume the extreme economic or practicable limit

of main opening to be 3 400 ft. or even 3 500 ft. For this last length the average weight of metal per linear foot of structure shown by the $E = 100\,000$-lb. curve would be 52 000 lb., which means that it would require 6.38 lb. of metal to support each pound of live load, exclusive of the effect of impact. This seems to be an excessive quantity; nevertheless, it is conceivable that conditions might exist which would render it advisable to adopt this extreme limit of main opening, although, at such a length, a suspension bridge is undoubtedly cheaper than a cantilever structure.

If it be admitted that—as is maintained by some bridge engineers—in structures of very long span the impact of the live load on the main members of trusses is essentially nil, the practicable limiting length of main opening will be somewhat increased. Moreover, such a contention is not far wrong, because the latest experiments on impact from live loads on bridges show that the effect thereof on ordinarily long spans is much less than engineers in general have been assuming during the last two decades. That the impact ever reduces actually to zero is most unlikely; but, for openings of 1 200 ft. and greater, it is true that its amount is so small as to be negligible, in view of the fact that the live-load stresses on the main truss members will never be quite as great as they are computed, because, first, the trains on the two tracks never advance together so as to produce maximum web stresses; second, such trains are not likely ever to cover entirely the bridge or even any individual part of it, except, perhaps, the central span; and, third, it is improbable that any load of cars, unless they be ore or coal cars, will ever be uniformly full and loaded to the assumed limit.

In Fig. 7 are given the curves of weights for cantilever bridges of the same type and loading as those used in preparing the curves in Fig. 6, excepting that the impact on main members of trusses is assumed to be equal to zero. The curves in Fig. 7 begin at main openings of 1 200 ft. and extend to the greatest practicable limiting lengths of such openings. A comparison of Figs. 6 and 7 shows that, by ignoring impact on trusses, there is, on the average, a saving of some 700 lb. of metal per linear foot of span, for all spans and all kinds of steel. This difference, curiously enough, is comparatively uniform for all the curves and over their entire lengths, with a few exceptions. At first thought, one might imagine that the saving should be greater

for long spans than for short ones, but it must be remembered that, as the span length increases, the percentage of live-load impact diminishes. It is this fact which makes the difference under consideration so uniform.

Under the assumption that the limit of weight of metal is 36 000 lb. per lin. ft., the greatest practicable span lengths have been

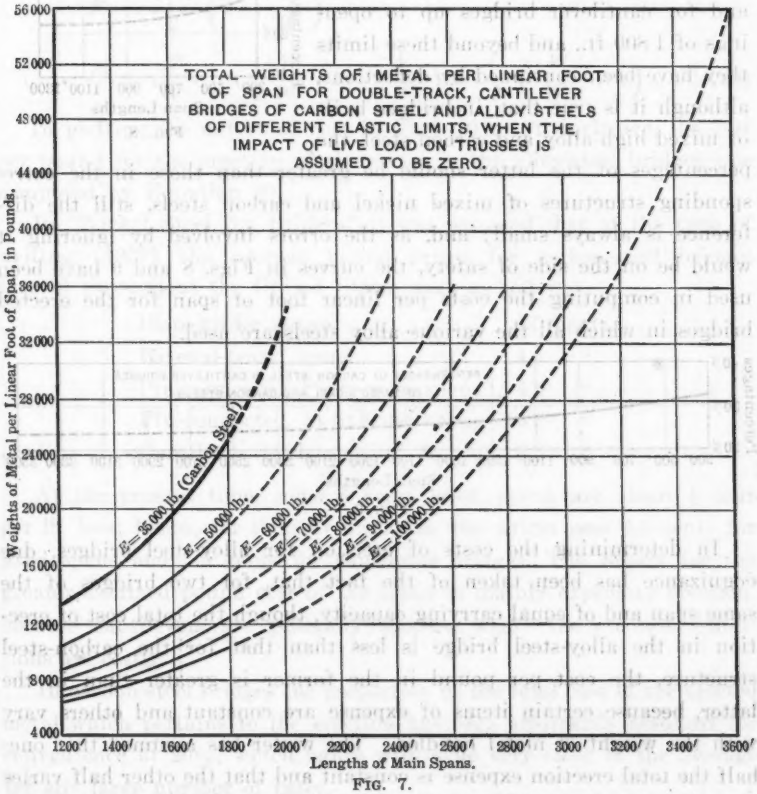

FIG. 7.

increased on the average only about 20 ft. by neglecting impact on trusses. Comparing the extensions of the curves for $E = 100\,000$ lb., it is found that, for an assumed limit of 52 000 lb. of metal per linear foot of span, the extreme practicable length of main opening has been increased only 25 ft. These various comparisons show that there is but little gain, either in economy or increase of practicable limit of opening, by neglecting the effect of impact; hence, in the economic

investigations which follow, the effect of impact has been duly considered.

In Figs. 8 and 9 are plotted, for both simple spans and cantilever bridges, the percentages of carbon steel in structures of mixed nickel and carbon steels. The curves are accurate for simple spans up to 600 ft. and for cantilever bridges up to openings of 1 800 ft., and beyond these limits they have been continued by deflections, although it is true that, in bridges built of mixed high-alloy and carbon steel, the percentages of the latter should be greater than those in the corresponding structures of mixed nickel and carbon steels, still the difference is always small; and, as the errors involved by ignoring it would be on the side of safety, the curves in Figs. 8 and 9 have been used in computing the costs per linear foot of span for the erected bridges in which all the various alloy steels are used.

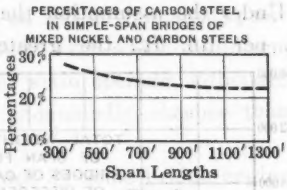

FIG. 8.

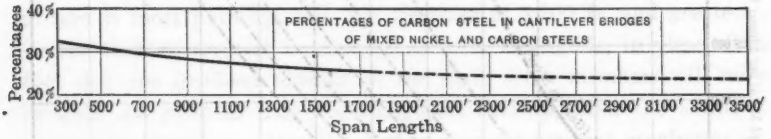

FIG. 9.

In determining the costs of erection for alloy-steel bridges, due cognizance has been taken of the fact that, for two bridges of the same span and of equal carrying capacity, though the total cost of erection in the alloy-steel bridge is less than that for the carbon-steel structure, the cost per pound in the former is greater than in the latter, because certain items of expense are constant and others vary with the weight of metal handled. The writer has assumed that one-half the total erection expense is constant and that the other half varies directly with the weight of metal. This is probably as accurate a division as can be assumed. On this basis was prepared, for the paper on "Nickel Steel for Bridges", the following mathematical statement:

Let W = weight of metal per linear foot of span in the carbon-steel bridge;

W' = ditto for the alloy-steel bridge;

C = cost per pound for erecting the carbon-steel bridge;

C' = ditto for the alloy-steel bridge;

F' = cost per linear foot for erecting the alloy-steel bridge;

then $C\ W$ = cost per linear foot for erecting the carbon-steel bridge.

$$F' = \frac{C\ W}{2}\left(1 + \frac{W'}{W}\right),$$

$$C' = \frac{F'}{W'} = \frac{C\ W}{2\ W'}\left(1 + \frac{W'}{W}\right) = \frac{C}{2}\left(\frac{W}{W'} + 1\right) \ldots\ldots (20)$$

In plotting the curves of cost in Figs. 10 to 21, inclusive, the cost per pound for the erection of the metal in the alloy-steel bridges was computed by Equation 20.

In "Nickel Steel for Bridges" it was assumed that at the time of writing (1907) the average pound prices for carbon-steel bridges erected throughout the United States were as follows:

Plate-girder spans	4.0 cents.
Riveted-truss spans	4.5 "
Pin-connected, Pratt-truss spans	4.5 "
Pin-connected, Petit-truss spans	5.0 "
Cantilever bridges	5.5 "

At the present time, some 6 years later, prices are about ½ cent per lb. less; hence, for this investigation, the writer uses 4.5 cents for fixed spans and 5.0 cents for cantilever bridges. The reason for the greater assumed pound cost of the latter is mainly expensive erection, because cantilevers are generally adopted where the erection conditions are costly.

In carbon-steel bridges the proportion of the total cost of the erected metal which pertains to the erection has been arbitrarily assumed for convenience at 20%, which figure will come very close to the average for any large number of cases.

The cost per linear foot for the tracks has, for convenience, been omitted in computing all curves, as it is constant and common to all spans; but, of course, their weight was included in estimating dead loads.

As no one can foretell what will be the excess costs per pound, delivered at bridge site, for the various alloy-steel bridges over the corresponding costs for carbon-steel bridges, in this investigation

FIG. 19.

various differences, beginning with ½ cent per lb., have been assumed; so that, for bridges built mainly of alloy-steel, of any elastic limit up to 100 000 lb., and for all practicable span lengths, in both simple spans and cantilevers, a comparison of cost of erected structure between that steel and all the other steel considered for all reasonable variations in pound price can be made either at a glance or very quickly by interpolation.

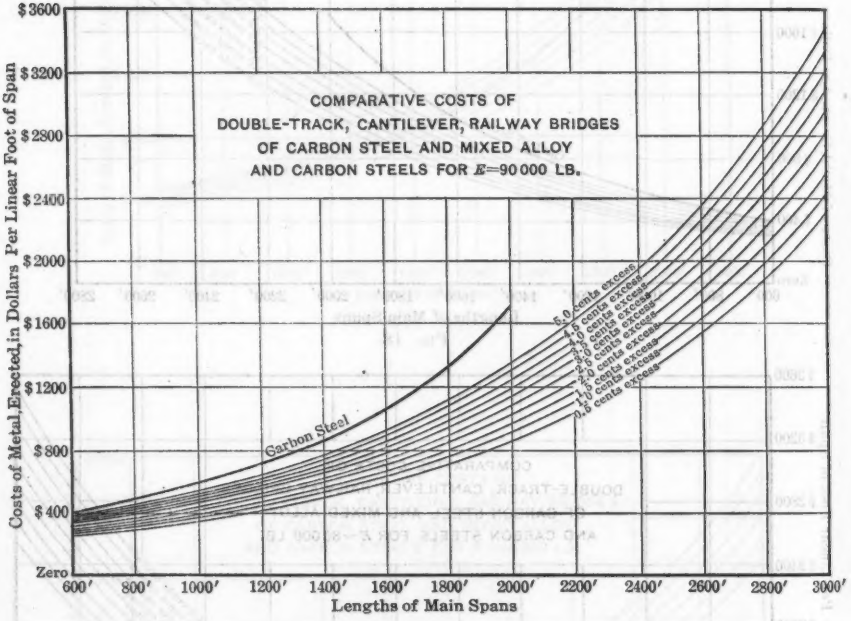

FIG. 20.

An inspection of Figs. 10 to 21, inclusive, will show how rapidly the costs of bridge superstructures increase as the practicable limit of span length is approached; also, that for very long spans an additional price of ½ cent or 1 cent per lb. is of small importance in the total cost of the structure.

In order to make evident at a glance the effect on cost of long-span cantilevers by the use of high-alloy steels, Fig. 22 has been prepared, on the basis of an assumed uniform excess cost of 2.5 cents per lb., delivered at site, for all alloy steels above the standard price for carbon steel, beginning with openings of 1 200 ft. and carrying the

curves out to the practicable limits of construction. This diagram indicates conclusively the folly of using nickel steel of an elastic limit of 50 000 lb., when, for practically the same price, an almost identical alloy having an elastic limit of 60 000 lb. is obtainable. Again, this diagram shows, for the different steels, the main openings for cantilever bridges, which, other things being equal, involve the same cost of structure per linear foot of span; it also shows how the differ-

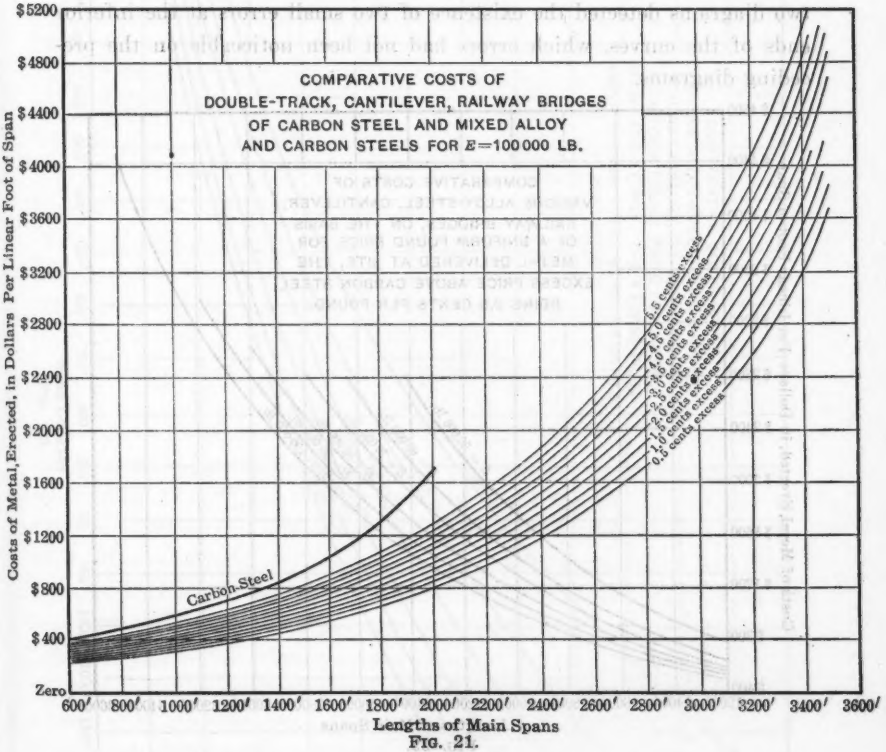

FIG. 21.

ences between the lengths of such main openings decrease regularly with the increase of elastic limit of the metal. Finally, the great upward tendency of the curve for $E = 100\,000$ lb. near its outer end shows that, for such an elastic limit, the extreme practicable span length is reached at about 3 500 ft.

In Fig. 23 is given the same information concerning simple-truss spans that is furnished for cantilevers by Fig. 22, *viz.*, a comparison

of costs of metal per linear foot of span for all the alloy steels, on the basis of adopting a uniform excess price over carbon steel of 2.5 cents per lb.

Incidentally, Figs. 22 and 23 afford an excellent check on the correctness of the writer's numerical computations; for, if there were any ordinary error made, it would be indicated at once by irregularity, either in the curves or their spacing; in fact, the plotting of these two diagrams detected the existence of two small errors at the inferior ends of the curves, which errors had not been noticeable on the preceding diagrams.

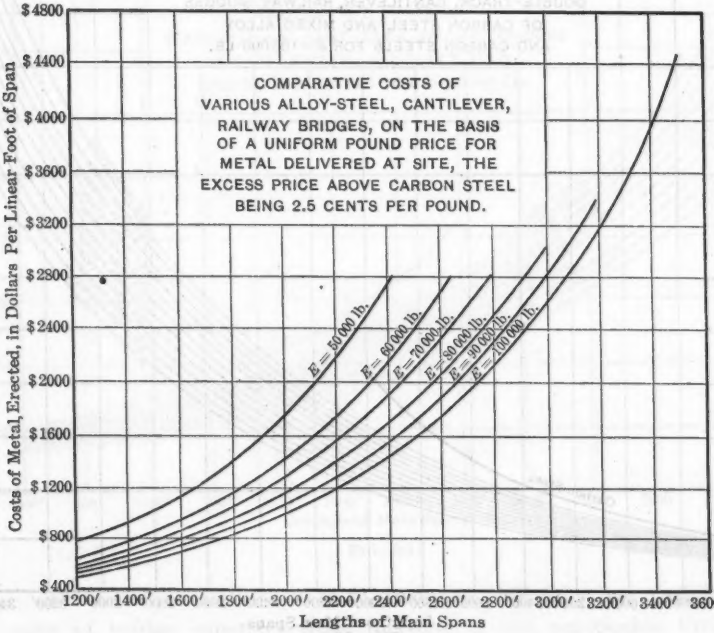

FIG. 22.

This brings up the question of the correctness of all the work in this investigation. There can exist nowhere any small errors of any importance, because they would have been detected at once by the lack of continuity in the diagrams. This feature, though, would not prevent the existence of fundamental errors based on incorrect assumptions or on wrong primary data. Such fundamental errors, however, are really impossible, because the weights of carbon-steel bridges dia-

Fig. 23.

grammed in the writer's office are very exact. Of course, the personal equation of the designer affects the weight of metal in structures designed by him, but this variation is confined to small limits. Again, the specifications used in the designing affect materially the weights, but the diagrams under consideration were all based on a single standard specification for carbon-steel bridges and on a similar specification for nickel-steel bridges. About the only place where the writer could have gone astray in this work is in the determination of the percentages of carbon steel in the bridges of mixed alloy and carbon steels. These percentages are subject to great variation, because no two designers would agree exactly as to what minor parts of an alloy-steel bridge should be made of carbon steel. This is a question which affects only slightly the diagrammed weights of metal, but does affect materially the diagrammed costs of structures. The curves giving the percentages of carbon steel in such bridges, as before stated, were prepared from diagrams of weights of metal in bridges of mixed nickel and carbon steels; and these diagrams were the result of careful, detailed computations of actual designs. The writer, consequently, feels truly confident in regard to the correctness of all the information which he is offering herein to the Engineering Profession.

Reference was made near the beginning of this paper to a method of producing nickel steel by adding ferro-nickel instead of pure nickel to the molten carbon steel, and to a statement by Mr. T. L. Willson that ferro-nickel containing 10% of nickel and nearly 90% of iron could be manufactured and sold at a profit at 2 cents per lb., thus making the nickel content cost only 10 cents per lb., and the excess price of the ingot nickel steel about 0.3 cent per lb. The extra cost of the shopwork is 0.15 cent per lb.; consequently the total cost of the manufactured alloy metal would be about ½ cent per lb. Referring to Figs. 16 and 17, using the lowest of the curves in each, it is found that there would be an economy in using the $E = 50\,000$-lb. steel varying for cantilever bridges from 13% in spans of 600 ft. to 20% in spans of 2 000 ft. For the $E = 60\,000$-lb. steel, the corresponding figures are 24 and 33% respectively. For simple-truss bridges, using the $E = 50\,000$-lb. steel, it is found from Fig. 10, that the saving varies from 16% for 350-ft. spans, to 32% for 1 000-ft. spans; and, using the $E = 60\,000$-lb. steel and Fig. 11, the corresponding savings are 26 and 44%, respectively. From the preceding figures of economy it is evi-

dent that it would pay the builders of large bridges to experiment with the use of ferro-nickel in the manufacture of nickel steel for bridge building, so as to determine whether the claims made by Mr. Willson in regard to its use are borne out by the facts.

The weights of metal for double-track railway bridges given in Figs. 5 and 6 can be utilized in estimating costs of any long-span railway bridges, because, if there be more than two tracks, the weights of metal per linear foot of span will, *ceteris paribus,* be directly proportional to the number of tracks. This is because, if only two trusses be used, the small saving in metal, in the trusses and the lateral system, will be offset by the extra weight of the floor-beams; and, if more than two trusees be adopted (as would generally be the case so as to avoid truss members of excessive cross-section), the economy of metal would be but slight.

Should a different live load per track from those herein used be desired, the weight curves on the diagrams can be modified accordingly by using the formulas in Equations 3, 4, 10, and 12; but, to do this correctly, one would need to know the division of total weights of metal per linear foot of span between the four components, "Floor System", "Lateral System", "Trusses", and "On Piers." Although it is not practicable, on account of space restriction, to give in this paper such a division with great accuracy, Tables 1 to 6, inclusive, will enable any one to calculate approximately, for any length of span and any kind of bridge herein included, the division of metal required.

However useful, though, may be the information given concerning weights of metal per linear foot of span for bridges in general, the principal object of this paper is to indicate the possibilities in bridge construction that may be attained by the use of high-alloy steels, and it is evident that the results of the writer's computations clearly prove that a systematic series of experiments made in search of a suitable and satisfactory alloy would be well worth while. Already it is practicable to obtain plate and shape nickel steel of 60 000 lb. elastic limit and eye-bar nickel steel of 65 000 lb. elastic limit; and, in the writer's opinion, it would not take much experimenting to raise each of these figures 10 000 lb.; but, to attain an elastic limit of 100 000 lb. or even 90 000 lb. for an alloy steel suitable for all shop manipulations is truly a great problem, and one worthy of much effort and a large expenditure of time and money.

The writer is of the opinion that the first step to take is to experiment on "purified" steel, so as to bring it to its maximum of effectiveness, then to try adding nickel in various quantities, and afterward nickel and other but cheaper substances. Of course, augmenting the quantity of carbon in the purified steel, while increasing both its

ultimate strength and its elastic limit, would tend to harden the metal; but the addition of nickel (and possibly other elements) would tend to reduce the brittleness and render it workable.

The problem of finding a high, cheap alloy of steel, suitable in every particular for bridges, is now before the metallurgists and the

builders of large metallic structures; and the values of all the results probably attainable are clearly indicated in this paper; hence the onus is on the Engineering Profession to see that the necessary experiments are arranged for and thoroughly carried out, in order that the world may have at its command a new metal that will permit of the spanning of waterways which are so wide and so deep, or are so restricted by navigation requirements, as at present to defy the art of the bridge engineer.

DISCUSSION ON VALUATION FOR THE PURPOSE OF RATE-MAKING.*

By Messrs. H. P. Gillette, C. B. Burdick, Wynkoop Kiersted, C. W. Hudson, Allen Hazen, and F. W. Green.

Mr. Gillette.

H. P. Gillette, M. Am. Soc. C. E. (by letter).—With very much of the Committee's report the writer is in accord. The most important of its recommendations is that entitled the "Equal-Annual-Payment Method", which involves reduction in the property value, according to the sinking-fund formula for depreciation, and the payment of interest on the residual depreciated value. This recommendation the writer cannot support. He concedes that it is possible to apply the method, under the ideal conditions tacitly assumed by the Committee, but he regards it as impracticable under conditions which actually exist, aside from the likelihood of its being unfair. Moreover, in view of the fact that when interest on sinking fund and on depreciated value are the same, the proposed method gives identically the same rates as would result from the application of a much simpler method, the writer fails to see wherein the complex method suggested by the Committee has any advantage. Its disadvantages are certainly pronounced and many.

The table on page 34 is used to illustrate the application of the Committee's proposed method of "Equal-Annual Payments". Column 2 gives the depreciated value, Column 3 the "depreciation during year", and Column 4 the annual interest on the depreciated value. The sum of Columns 3 and 4 is the total depreciation and interest

*Continued from February, 1914, *Proceedings*.

Mr. Gillette.

for the given year, as shown in Column 6, which is seen to be a constant. Thus, at the age of 10 years, we have:

Depreciation (on $61.96)	$4.93
Interest, 5% on $61.96	3.09
Total	$8.02

This depreciation of $4.93 is the annuity that would amortize the $61.96 in the remaining 10 years of life. This calculation is entirely in accord with a principle laid down by the writer, 4 years ago, in his "Handbook of Cost Data", namely:

"The owner of a second-hand machine is entitled to such a price for it as will enable the purchaser to go on with its use and produce each unit of product at as low a cost as the average unit cost of production would be during the entire life of the machine."

Column 6 of the table on page 34 shows that this condition is fulfilled, and interest and depreciation are a constant amount ($8.02) throughout the life of the plant unit. It follows, therefore, that rates or prices for service would be unchanged, due to depreciation. For this principle of unchanged rates the writer has long contended; but, unfortunately, when a depreciated value has been used as a basis for rate-making, the rate-making body has not recognized the fact that the shorter remaining life of plant units logically necessitates a correspondingly higher depreciation annuity. In other words, rate-making bodies have invariably taken a depreciation annuity based on the full life of plant units, and then, when they have used depreciated values for rate purposes, have applied that annuity to plant units, part of the life of which has expired—a logically indefensible procedure. If depreciated value is to be used as a basis for rate-making, it becomes necessary for engineers to apply correspondingly higher rates of annual depreciation, because of the shortened time during which the owners of a utility are forced to recover their remaining capital. The public, it will be seen, will not gain in lowered rates when this is done; and will then cease to be so eager to assign a depreciated value to utility plants.

If the writer interprets the Committee's attitude correctly, he cannot see that it offers a better method than has hitherto existed for rate-making. The old plan has been to keep the capital intact, always paying interest plus profit (= fair return) on the full investment, and always providing for repairs and renewals out of earnings. In the case given as an illustration, on page 34, this end would be attained by adopting an unchanging depreciation annuity of $3.02 and an unchanging interest of $5.00 on the full investment of $100. Let us consider some of the practical difficulties that would arise were this method abandoned in favor of the Committee's method.

Mr. Gillette.

First, according to the Committee's recommendation, there would be no depreciation fund or replacement reserve; but the utility company would be at liberty to distribute the depreciation annuity among its owners. This carries with it the necessity of calling in stocks or bonds to the amount of the depreciation annuity thus distributed. Conversely, as soon as any renewals of plant units would be made, new securities would be issued. Such a constant flux of securities seems to the writer impracticable for many reasons, which need not be mentioned, as they will be evident on reflection.

Second, the accrued depreciation is entirely a function of the estimated life of each group of plant units, according to the Committee's method. This assumption, however, is not justifiable except for natural depreciation. In the case of accrued functional depreciation (due to obsolescence, inadequacy, etc.), it is impracticable to estimate accrued depreciation by any formula that recognizes only the age of plant units. There is only one accurate method of estimating accrued functional depreciation, namely, by comparison of the unit costs of the product or service rendered, using, as a basis for comparison, the most economic plant unit available. This is a special case of the Unit Cost Formula for Depreciation, which the writer has recently discussed at length elsewhere.*

Even engineers are not always aware that most of the "lives" of plant units given in tables are not natural but functional lives. It is probable that the average functional life of all plant units of utility plants in America has been less than 20 years, whereas the natural lives of many of those same units is so great that as yet no engineer can fix their limit.

Thus, locomotives have had a functional life of about 20 to 25 years in America. In Europe, the functional life has been far greater, due to the slower growth of traffic and to other reasons. What is the natural life of a locomotive? No man knows. Stevenson's second locomotive is still in use in an English colliery, after more than 90 years of continual service.† Engineers have deceived themselves, and have unwittingly deceived others, by publishing tables of the lives of plant units without stating whether it was natural or social forces that limited those lives. The writer has come to have less and less confidence in statements as to lives of plant units when nothing is said as to the conditions and causes that have operated to limit such lives. Yet how rarely is a word given in explanation of those conditions and causes. To say that cast-iron pipe averages 50 years of natural life, for example, is to say what no man can prove; first, because pipe-life data are too meager to be entitled to use in striking an average; second, because short functional life has served so generally

* *Engineering and Contracting*, Oct. 30th, 1912; and *Electrical World*, Nov. 2d, 1912.
† *Engineering and Contracting*, Oct. 11th, 1911.

Mr. Gillette.

to obscure the fact that the natural life is long. Finally, the writer refuses to be bound by averages of any kind as applied to a special case unless it can be shown that the special case itself conforms approximately to the average.

The bearing of all this on the question before us is plain. The Committee suggests a method that involves the calling in of stocks or bonds, and re-issues of the same, depending on some engineers' guesses as to the probable life of many plant units, and, in most cases, the guess relates to functional life.

It will be answered that a guess as to life of plant units must be made in any event, if a depreciation fund is to be established, and that such a guess must involve guessing at functional life. This is true; but there is a marked difference between establishing a depreciation fund that shall be ample, and establishing a depreciated value that shall be fair to an investor whose capital is at stake. In the case of a depreciation fund, an error one way or the other can be rectified. If experience demonstrates, for example, that too large a fund has been accumulated, then depreciation annuities can be reduced. This can happen without injustice to the public or to the public utility company; but, let a mistake be made in calculating depreciated value, let interest distributions be based on an erroneous depreciated value, and a serious injustice may be wrought.

In the writer's opinion, a depreciation fund should be built up especially to provide for functional depreciation; also, to provide for renewals of plant units having a long natural life. For plant units having a short natural life, and where such units are of all ages, such a fund is seldom needed. A depreciation fund is, in essence, a device whereby the original investment is to be preserved intact. As a member of the Pennsylvania Public Service Commission aptly put it: "This is only a method of underwriting the investment."

As previously indicated, the third serious objection to the method proposed by the Committee arises from the necessity of great accuracy in estimating accrued depreciation. This accuracy is not limited to the time of the initial appraisal, but must be perpetual, for the repeated calling in and re-issuing of securities to avoid over-capitalization involves very accurate determination of accrued depreciation when the latter is to be the basis for capitalization. Accuracy in applying a sinking-fund formula for accrued depreciation involves opening a separate depreciation account with every group of similar plant units at the time the group is put into service. It is not correct to use "composite lives" and "composite ages" in calculating depreciation annuities for a sinking fund. Thus, a group of 1 000 poles, 10 years old, cannot be averaged with a similar group 2 years old, and a depreciation annuity calculated for the total life minus the average age of 6 years.

Mr. Gillette.

The fourth objection to the Committee's method is touched on by the Committee itself. A serious difficulty with its "Equal-Annual-Payment Method" arises when the rate of interest used in calculating the depreciation annuity differs from the rate of "interest" (or fair return) on the depreciated value of the plant. Then, as shown in Column 7 of the table on page 34, the "equal-annual payments" cease to be equal, and become progressively less until the plant unit is renewed, when they jump up again. The Committee thinks, however, that current repairs will rise rapidly enough to offset the diminutions shown in Column 7 of the table, but in this it errs. Suppose the plant units having the 20-year life assumed in the table are cedar poles, or any other sort of units not made up of short-lived parts. Then, assuredly, the Committee's assumption of rising repairs fails of fulfillment. Again, let the 20-year life be a functional life (not a natural life), say, of an electric generator or of a railway bridge or station, then long before the age has become great enough to cause much of a rise in the curve of repairs, the entire unit is retired. Under one of these two classes falls most of the investment in plant units of railways and other public utilities. Hence the method advocated by the Committee fails to accomplish the result that it was its aim to accomplish, namely, equal annual payments, and, therefore, stability of rates charged for service. It would seem, then, that the Committee's method results in the very predicament that other engineers have objected to, namely, variable rates for service if depreciated value is the basis for rate-making. The Committee's criticisms, therefore (see pages 48 and 49 of its report) of the views of other engineers on this matter are not entirely answered when it presents a method which is itself subject to the same criticism.

Apparently, the Committee's main objection to using the new value of a plant as one of the elements in rate-making, arises from the belief that by so doing the public will be made to pay twice for the accrued depreciation. The writer's experience thus far has been that the public has rarely or ever recouped the railways and other utility companies for the accrued depreciation. Depreciation funds seldom exist, and, where they do, they still more seldom equal the accrued depreciation. What is more significant, however, is the almost universal development cost, or accumulated deficit in fair return, that railways and other utilities disclose when their accounts are properly analyzed. When, in calculating development cost (= the "going value" of the Wisconsin Railroad Commission), a depreciation annuity is allowed as a part of the past operating expenses, sufficient to provide for the accrued depreciation shown by an appraisal, it is a rare occurrence when the development cost does not more than equal the accrued depreciation. This is one of the surprises that a much deceived public is to receive. Muck-raking articles based on the flimsiest of evidence,

Mr. Gillette.

grossly distorted, have created a very general impression that nearly all public utility stock is badly watered, and that enormous profits have been universal. Engineers, who should know better, are not entirely free from a bias created by this false "testimony".

Accrued depreciation receives its proper consideration in calculating development cost, or the cost of establishing the business. The writer has discussed this matter at some length elsewhere* and, therefore, will not go further now than to caution against a blind adoption *in toto* of the Agency Theory on which the development-cost calculation rests. Although it is wise to determine what would be the total investment (physical and non-physical) according to the Agency Theory, it should not be forgotten that the theory has evolved slowly and is comparatively new. To what degree a new theory can rightly be made retroactive is a matter for serious consideration.

These and other difficulties confront rate-regulating bodies which aim to be fair. As yet there seems to be no escape from the necessity of weighing all the facts bearing on value as well as on cost, as outlined in Justice Harlan's celebrated decision (1898) in the Smythe *v.* Ames case.

The Committee's report indicates an effort to compromise between the Agency Theory and the Replacement Theory, by taking past conditions and present prices. Is it not better not to mix the theories, but to present the results of each theory complete and logically derived? Then the final "rate-making value", which is likely to be a compromise, will be arrived at after weighing all the evidence. The engineering mind usually rebels at a compromise of any sort, but in appraisal cases compromises are almost inevitable, primarily, because we are in a transitional period. The old Competitive Theory is rapidly being modified by the new Agency Theory of rate regulation. Not only does each theory have its merits, but it is impracticable to make the new theory entirely retroactive without working grave injustice in many instances.

Mr. Burdick.

C. B. BURDICK, M. AM. SOC. C. E. (by letter).—This report is particularly opportune, for we have just entered an epoch of rate regulation; and the valuation of the railroads lately undertaken by the Interstate Commerce Commission has directed many able minds to the subject for the first time. It is not surprising that, under these circumstances, many ideas strongly advocated are very discordant with one another. To the casual observer it might seem that the principles of valuation are in a very chaotic state, or, as the Committee expresses it, that they are in a developmental stage. The principles involved, however, are much more clearly established at this time than appears on the surface.

* *Engineering and Contracting*, June 26th, 1912.

Mr. Burdick.

The Committee has apparently attempted to formulate a procedure for fixing an equitable value that may be used in the matter of rates, by considering each item of value by itself, as to its equity or inequity, on the assumption that, if the parts are equitable, the sum of the parts must be. The defect in this procedure lies in the impossibility of determining what is equitable in most cases until after all the parts have been summed up and considered in the light of all facts having a bearing on value. When the sum is obtained, it represents nothing in particular. It is neither present cost of duplication, nor investment, and probably very imperfectly represents value.

It will greatly clarify the discussion to decide at the outset whether the fair return to be established shall apply on investment or on the value of the property.

If public utilities were not yet established, it would seem entirely equitable to all concerned to provide that the rates should be based on a fair return on reasonably wise investment. The public could have no cause for complaint, and the investor, being reasonably sure that his investment would be protected, would probably be content with a low rate of return. Eras of high and low prices would affect injuriously neither the investor nor the public. Those looking for large profits would invest elsewhere. However, no such situation exists. In practically all cases at this time we are dealing with established properties, nearly all of which antedate the epoch of rate regulation and the Court decisions based on public policy that have made rate regulation possible. The Constitution of the United States provides that private property shall not be taken for public use without just compensation.

The Courts, which must be our guide in the interpretation of the law, are very firm that rate regulation shall be based on the value of the property concerned and, therefore, in valuations for rate-making purposes, it is the duty of the appraiser to determine value as nearly as can be done under the circumstances existing at the time of the inquiry.

How, then, shall we measure this value? The Courts are authority for the belief that cost of duplication under present circumstances is an important measure; that the actual investment should be considered; that even the stocks and bonds and the revenues derived from operation are not without the pale of consideration; that all these should be given their proper weight, under all circumstances, in throwing light on the value. Further, that the value must be reasonable to the buyer and seller, and, in the case of rates, that they must be equitable under all circumstances to the owner and the public.

In various cases involving property the Courts have held that the owner is entitled to the accretions in its value from whatever causes they have arisen, and if the property has depreciated that must be taken into consideration, if for any reason the property must be

Mr. Burdick.

valued. The owner must receive the benefit and suffer the loss of value. In taking his property for the public use he must be remunerated for the property as it exists at the time taken. In fixing values for the purpose of rates and values for the transfer of ownership, it would seem that value in the two cases is one and the same thing, the fair present value of the property; and, so far as observed, the Courts have made no important distinction in the values for these two purposes.

For the same reasons of public policy that permit rate regulation, it is to the public interest that wise investment should be reasonably protected. The property must be allowed to earn rates that will enable it to be self-supporting. It is in the interest of public policy. Unless the property may earn such rates, the service cannot exist. Therefore the Courts have expressed an interest in the amount that has been invested and are loth to fix values, or rates of return, or both, which would tend to discourage investment in like enterprises. For the same reason inquiry as to the stocks and bonds is pertinent, and though the individual security holders cannot be protected against the operations of frenzied finance, the reasonableness of the financial operations can be determined in the light of the figures on investment and cost of reproduction. What light would be thrown on the matter by an estimate of the cost of reproducing the property at present prices under the "conditions existing at the time the various portions of the property were built?" It would throw light neither on the investment nor on the present reproduction cost of the property.

It would seem that the Committee has shown a leaning toward investment as a measure of value for purposes of rate-making, but through the influence of Court decisions, which are numerous and strong, had been forced to the adoption of present prices in the estimates of value. This, it is believed, has placed it in the indefensible position (Conclusion 7) of reproducing the property under the "conditions existing at the time the various portions of the property were built, but on the prices prevailing at or near the time of the valuation." This amounts to assuming part of the circumstances in the past and part in the present, for unit cost is as much a circumstance of the time as any other element subject to change with time. In justification of this conclusion, a case was cited of a reservoir in the construction of which a railroad track was necessarily moved to a new location, the cost of removing the track being properly included in the value of the reservoir. The conclusion is further applied to exclude pavements laid over water pipe after the pipe is laid, and to include the extra cost of "piecemeal construction" in computing the value of water mains. It does not require this general conclusion to justify the inclusion of the railroad track. If we reproduce under the circumstances of the present, we are bound to assume reasonable conditions,

Mr Burdick.

and if a railroad formerly occupied the site of the reservoir, it would be entirely reasonable to assume that it would necessarily be removed in reproducing at the present time, unless there should be good reason to assume otherwise. In reproducing such a reservoir, it would be necessary to assume the contour of the ground, and one could be guided in such assumption only by approximating conditions known to have existed in the past. In this case the past is a guide to reasonable assumptions for duplicating under present circumstances. The cases of pavements and "piecemeal construction", the exclusion of the former and the inclusion of the latter, in the sum total of value, are reversions to past cost or investment, and would seem to have no place in present cost of duplication or present value.

It would seem most logical in the valuation of these properties to pursue one logical method through to the end. If it be the cost of duplication at present, then reproduce under present circumstances, and when the figures are summed up, one will have a total that represents something tangible—the cost of duplication. If it be past cost, an estimate of the investment, then follow past cost consistently to the end, and the total will represent investment. Neither total will necessarily represent value, but the two will point strongly toward it, particularly if they are not far apart.

The Courts state that the rates produced must be equitable both to the owner and to the public, and it is here that an opportunity is offered to test the reasonableness of the totals previously determined. If fair rates of return applied to the total cost of reproducing the entire property necessitate rates that are reasonable to the public, then all the equities are satisfied. If the rates necessitated are unreasonable, then the value or rate of return must be reduced to such amount that the inequity is distributed in a just way between the owner and the public.

In some cases the foregoing procedure is difficult, but in most cases an equitable decision is the result of industry and intelligence in marshaling all the obtainable facts and common sense in their application to the problem particularly in hand. It is not a task for a novice. It requires broad experience in every important phase of the property to be valued, an open mind, and some considerable acquaintance with the subject of valuation in general. A realization of the truth stated by the Committee, that rates too low are unjust to the public, is helpful in establishing justice.

The Committee frankly states, after pointing out the necessity of following the Courts:

"And while your Committee has been guided largely by the decisions of the higher Courts and public service commissions, it recommends what seem to be sound views and desirable changes in practice, even though not wholly in accord with such decisions."

Mr. Burdick.

Is this a wise position? Has the Committee had the opportunity to consider the matter sufficiently to warrant it in recommending procedure at variance with the law as established by the higher Courts? The law is the outgrowth of the experience of centuries. It is necessarily modified from time to time as new conditions arise. A great concession in favor of the public was made when rate regulation was permitted in the face of existing contracts, but the Courts stand firm as a rock against some of the views advocated by the Committee.

Mr. Kiersted.

WYNKOOP KIERSTED, M. AM. SOC. C. E. (by letter).—The writer has been very much interested in studying this report, which is certainly instructive; but, before the Committee makes its final report, it is hoped that the application to a composite property of the Equal-Annual-Payment Method as well as of the other recognized methods of computing depreciation will have been shown.

The question of rate-making requires the ascertainment, among other things, of a fair earning value of a public utility and a rate of return thereon which is fair to the investor and to the public, and which will provide a fund for replacements and renewals to an extent which, when invested in replacements, will maintain the property in an efficient condition and will protect the original investment. The decision of the United States Supreme Court in the Knoxville case appears to confine the fund for depreciation to replacement of units to an extent which will maintain the original investment unimpaired. Such replacements are expected to be made periodically as needed to keep the property in an efficient operating condition, and when so made it is difficult to escape the conviction that a property thus maintained should be entitled to a return on substantially a 100% value. The writer expressed this view a little more in detail in his discussion of the paper* by John W. Alvord, M. Am. Soc. C. E., on "The Depreciation of Public Utility Properties as Affecting Their Valuation and Fair Return". To what was said in that discussion may be added the suggestion that the earning value of a composite property, made up of the earning value of its units, is not affected by consideration of age as long as repairs of the unit and replacements of parts of the composite property receive timely attention. A unit, retained as a necessary part of an efficient property, possesses a 100% earning value, whether old or new, quite as much as the composite property itself. The question of accrued depreciation, as applied to either the value of the unit or the value of the composite property, does not arise for consideration in a rate case as it does in a valuation for purchase and sale.

The life of a unit of a composite property depends on such a variety of conditions as to be indeterminate with precision. The best evidence in this regard is that furnished by a study of the cost of

* *Proceedings*, Am. Soc. C. E., February, 1914.

operation, maintenance, and replacement of properties which have been in use long enough to afford a wide range of operating conditions. Such information collected from each class of property, properly analyzed, should be the best guide as to the proper rate of return on an investment to cover the cost of replacements. Doubtless a large amount of information of this character has been accumulated through various sources, which should aid materially in the solution of such problems. Mr. Kiersted.

Although the rate of return as interest or dividends, and as profits, may be practically uniform for some classes of property in particular districts, it does not follow that the rate of return to supply a fund to take care of replacements shall be correspondingly uniform. For instance, a public utility in a rapidly growing city requires proportionately heavier expenditures in replacements during the earlier than during the later periods of its existence, whereas the reverse may be true of a slowly developing utility in a slowly growing city. The rate of return for replacements in one case should evidently be more liberal than in the other. Moreover, many physical conditions and service requirements will have a modifying influence to an extent which requires a close analysis of the individual property.

Any method dealing with a rate of return on a public utility, considered as a whole, must be based finally on equal annual payments, and will be divided essentially into two parts, namely, a rate of return to the investor as interest or dividends, and as profits, and a rate of return to cover replacements. As long as the rate of return is equitable for both purposes, it does not matter what the detailed analytical methods may have been in reaching a conclusion, if that conclusion is substantially correct. In order to reduce the probabilities of error of individual judgment as much as possible, it were perhaps as well that the analytical methods, taking into consideration the units of a composite property, should embrace the use of the several rules or mathematical formulas rather than that of only one rule or formula.

The valuation of portions of a physical property on the basis of present value under original conditions, and other portions on the basis of present value under present conditions, introduces an uncertainty as to whether such a distinction should be made, and, if made, whether the reasons therefor are sufficient to justify the distinction. Furthermore, the unearned increment included in an item of property, particularly real estate valued under present conditions, raises the question as to the extent which this unearned increment of value is to be considered in a rate case, and whether, if considered, it should earn a rate of return equal to that of other portions of the physical property, barring a return for replacements. Still further consideration is open to the question of whether such an item of property as real estate, possessing value independent of the public utility with which it may be associated, by reason of urban surroundings and asso-

Mr. Kiersted.

ciations, is subject to the same degree of hazard of ownership as that attaching to other items of property possessing practically no value except as a part of the public utility. If the hazard in the one case is less than in the other, should the owner be entitled to as great a return on the portion of his investment involving little or no hazard as on that portion involving a positive hazard?

Mr. Hudson.

C. W. HUDSON, M. AM. SOC. C. E. (by letter).—It appears to the writer that the Committee should have confined its report to the field for which it was appointed. Undoubtedly it will be conceded that engineers have special knowledge on the subject of cost of reproduction of the physical elements of public utility property. Assuming that the Committee has been able to formulate principles and methods which will be of use in determining the value of the property of railway and public utility corporations, it by no means follows that it has been or that it will be able to show how the values thus determined may be used to fix rates.

In the case of a public utility engaged in supplying one commodity to a limited district, the cost of the service may bear quite a close relation to the value of the plant, and in so far as that value affects the reasonableness of rates for service, it might be taken as the cost of reproducing new, the cost of reproducing new less depreciation, or the amount of capital invested. For the case of railway property, which is used under such varying conditions and, in the aggregate, represents nearly one-sixth of the wealth of the nation, it will not be possible to establish to the satisfaction of a majority of the members of this Society a working relation between value and rates.

The making of the tariffs of the railroads is in itself such an intricate and extensive subject, involving as it does the stability of our entire economic structure, that the writer does not believe the Committee was warranted in trying to formulate principles of valuation for rate-making. It is certain that a careful study of the report does not show how it would be of the slightest service in the preparation of proper railway tariffs.

Numerous reasons may be cited to show that even the cost of the service, which includes the value of the plant, should not always determine the reasonableness of a rate. An important requisite is that the traffic must move; that is, that the rate for the service shall be low enough to allow it to move.

The Committee does not appear to include the most valuable elements in its valuation for rate-making. To quote from the report:

"Justice and equity require that in any regulation of rates fixing the amount which may be earned by a public service corporation there shall be taken into consideration two distinct features:

"First, the annual return covering interest and profit, to which the corporation is entitled for the use of its capital, having in view the risks incidental to the investment. Mr. Hudson.

"Second, an allowance sufficient to provide for the net depreciation in the value of all the items of physical property, whether resulting from decay, wear and tear, or other cause, the amount of such depreciation allowance to be sufficient to amortize all such items of property by the time they cease to have value."

In other words, the Committee would be willing to insure the railways an attractive earning capacity based on these two considerations. To the writer's mind, the owners of railway property could lie down and rest in perfect repose as far as any fear as to what their competitors were doing was concerned. Every business enterprise in order to succeed must have brains, honest labor, and loyalty back of it. To base a rate for service on any consideration of value of the physical plant alone, leaving out the more important factors, would be a great economic mistake, and it will be a serious error for the United States to do any such thing.

It also appears advisable to the writer to separate the rules and methods for valuing public utility properties from those for valuing railway properties.

He does not believe it will be possible for the members of this Society to come to anything like a general agreement as to how railway rates are to be fixed. Very few of them have an extensive knowledge of the subject, nevertheless, there are probably many members who are willing to take it out of the hands of experts. The writer wishes to express his conviction that the Society should not publish any rules for valuation for the purpose of rate-making.

ALLEN HAZEN, M. AM. SOC. C. E. (by letter).—The writer has the feeling that under the heading, "Present or Original Conditions", the Committee has given more attention to the history of the plant than is fairly justifiable. For instance, in estimating the cost of reproduction of a water-works plant, the cost of cutting through the paving of the street over it, and replacing such pavement after laying the pipe, is unquestionably a part of the cost of reproduction, and must be included in any true estimate of it. The Committee, however, would exclude all that part of the cost which relates to paving laid after the pipe was placed. The writer is unable to see that the question of whether the pipe or the paving was laid first has anything to do with the cost of the reproduction of the property as it now stands, or with its value. It would cost just as much to replace the pipe in one case as in the other. The value of the property, as measured by its capacity for useful service, is identical in both cases. Mr. Hazen.

This procedure, together with others in the report, seems to have been adopted by the Committee in an endeavor to get at something

Mr. Hazen.

that may be taken as the equivalent of "invested capital" to be used in place of the actual amount of the investment, which may be unknown. The impression is given that the Committee had in mind something like the following: What amount of capital might reasonably have been invested in the enterprise, assuming that the prices of the last few years had obtained during its entire history? This idea seems to have displaced to a considerable extent that of the cost of reproduction.

Going a little further, the distinction between cost and value does not seem to be made, and the whole report seems to be directed to consideration of cost. So far as the writer can find, value is not considered in it at all. It may be that in a subsequent report the relations of cost to value will be discussed. Otherwise, it would seem better that the title of the report should be changed, and that cost, or cost of reproduction, should replace the word "valuation" in it.

Mr. Green.

F. W. GREEN, ASSOC. AM. SOC. C. E. (by letter).—This report is a notable addition to the literature on one of the momentous matters of the day, and the comprehensive, and withal temperate, treatment by the Committee of so difficult a subject is, in every way, praiseworthy. A thorough discussion undoubtedly will assure a more perfect understanding of the matter; and a clear understanding must precede a perfect judgment.

The attitude of a very considerable number of persons toward the railways as a whole is suspicious, if not hostile; it seems to have been reached by a most unusual method of logic: (1) *A, B,* ..... *Z* are railway companies; (2) *A* and *J* have been corrupt, inefficient, and arrogant; Conclusion: *A, B,* ..... *Z* have been corrupt, etc. This is a general conclusion from a specific premise.

Again, assume two roads, *X* and *Y*. Road *X* was honorably conceived, constructed, and operated. It replaced its equipment and maintained its plant from adequate reserves from earnings, and it was not necessary for it to capitalize such replacements and maintenance. Road *Y* pursued the opposite policy. Should *X* be condemned for the sins of *Y*?

Two issues present themselves in connection with the consideration of the unearned increment in land values. If other land owners are permitted to enjoy this increment, may railways justly be deprived of it? If railways are not to have equal benefit of the laws, why does the State assess taxes on the basis of the increased value? This brings up the matter of the railway charter. In the usual form, it is in the nature of a contract between the State and the corporation. On the part of the State there is the obligation to do certain things, namely, the grant of authority to buy and sell, to contract, to exercise the right of eminent domain, to locate, construct, and operate a railway, to sue and be sued, etc.; and, on the part of the corporation, in return for

Mr. Green.

these grants, it agrees to do certain things, namely, to furnish adequate transportation service, at reasonable rates, and without discrimination; and this implies the development of new country, the increase of private and public wealth flowing therefrom, and the foundation for a large unearned increment for those land owners who may be fortunate enough to be located near the new development. Some writers aver that the increment in railway right-of-way values is the result of the community development; but if this is so, what caused the community development in the first place?

As to the various Court decisions, it is the writer's belief that in some instances these have erred, either from a failure to present the issue to the Court in terms of the Court's comprehension, or from failure of the evidence to clarify and illuminate the issue with sufficient detail. It is no uncommon experience for engineers to have great difficulty in communicating a more or less technical matter to eminent lawyers in such a way that it will be clearly understood. Again, there appear to have been some cases, at least, in which the issue was confined to the consideration of the strictly legal aspects of the case, rather than to the matter in its economic aspects.

The matter of efficiency of operation and special advantages of location is of absorbing interest. If the well-located line is denied a reward for efficient management, there will be no incentive for it, and the public will be required to contribute to the extravagance resulting. Again, if the rates are to be measured by the amount required to sustain the strongest line, what will become of the weakest? If the rates are adapted to the necessities of the weak line, will not the strong line enjoy inordinate profits; or, if a fat rate is permitted on the weak line, and a lean rate on the strong line, will not development move along the line of least resistance, and population and traffic increase on the strong line and decrease on the weak line? If so, will there not be a discrimination established between communities, which will produce much more public discontent than under the present alleged unsatisfactory conditions? It is along these lines that the real difficulties of applying the theory of making the rate a function of the valuation become apparent. The Committee has very wisely remarked that other considerations should enter into the subject of rate-making. It may be pertinent to mention some of them: The competition of carriers; the competition of commodities; competition of communities; value of the service to the patron; cost of performing the service; density of traffic; direction of traffic; volume of traffic; carload minima and maxima; slow or fast movement required; and insurance as carriers.

As to depreciation: Some hold that rates should be based on the depreciated value of the property, unless and except, the depreciation fund in cash is kept on hand intact, and so denominated. The usual

Mr. Green.

argument is that, if such fund is not thus kept and labeled, there is a return of capital to the owner of the utility, and hence the capital invested in the first instance is withdrawn and available for reinvestment. It is to the user's interest that the property be maintained, both with regard to adequacy and economy. As long as efficient service can be given, the user should expect to pay to the owner as much for the same service on an old road as on a new one; and as there is no requirement that maintenance be paid for out of any other than the general funds of the owner, and further, because adequate maintenance is, or should be, a prior lien on such funds, there would seem to be no justice in making the rate fluctuate with the variations of physical condition. Moreover, if it is conceded that there is in effect a return of capital to the owner, does not this carry with it the implication that it would be permissible for the owner to capitalize maintenance charges when made, and would this not be in violation of the principles of accounting established by the Interstate Commerce Commission?

It is to be hoped that in due time will come recognition of the economic truth that the welfare of all depends on the just and equitable treatment of each unit in the body politic.

ROAD CONSTRUCTION AND MAINTENANCE.

An Informal Discussion.*

By Messrs. Nelson P. Lewis, John C. Trautwine, Jr., William Goldsmith, George A. Ricker, George W. Tillson, Robert A. Meeker, R. E. Beaty, William M. Kinney, D. B. Goodsell, H. W. Durham, Herbert Spencer, T. Hugh Boorman, and Philip P. Sharples.

ENGINEERING ORGANIZATIONS FOR HIGHWAY WORK.

Nelson P. Lewis, M. Am. Soc. C. E. (by letter).—It being admitted that an engineering organization is required to deal with highway work, it follows that the details of such an organization should be determined by engineers. The time has passed when engineers should be expected to carry out municipal work of any kind when they are told, as they are told, and because they are told. Municipal engineers must assume the responsibility of determining, not only the kind of organization through which this control is exercised, but the general policies of a city with respect to such work. Every city needs a definite plan and programme. The need of a comprehensive plan for a street system is now generally recognized, but it is not as generally recognized that this should be the work of the engineer. A paving programme is just as essential. The policy of most American cities has been to leave the kind of pavement to be laid on any street to be determined by the abutting property owners, on the ground that, as they are to pay the bills, they are entitled to say what kind of pavement they should have. Such a plan cannot result in a well-paved city. By a well-paved city is meant a consistently paved city, that is, a system of pavements in which the surface on each street is determined by the grades, the traffic, the development of the abutting property, and its ability to pay. If grades permit, it is desirable to have

Mr. Lewis.

* Continued from February, 1914, *Proceedings*.

Mr. Lewis.

the same kind of pavement on a continuous thoroughfare, and it is very desirable that the driver of a team should be able to follow a pavement on which horses can travel under any weather conditions from any part of a city to any other part.

There should also be a definite plan for the location of sub-surface structures. The building of pipe subways has frequently been urged as the only means by which an orderly arrangement of underground structures can be secured and the constant opening of the street surface prevented. When a new street is being built or an old street is being widened and entirely reconstructed, the placing of pipes and conduits in subways may be practicable, but, unless all these pipes are new, and unless the greatest care is exercised to prevent leakage, especially of gas, the risk of carrying out such a plan is considerable. Paris no longer permits electric wires to be placed in the sewers, where the water and gas mains are accommodated, but separate electrical conduits are usually placed under the sidewalk. This, again, is a subject for careful engineering investigation, and is worthy of assignment to a place in an engineering organization dealing with highway work.

In the opening discussion, the city highway bureau was aptly described as the principal show-case of the city government, the pavements representing the goods in the window. It follows that there is no department of municipal work where inefficiency is so sure to result in criticism as in the highway bureau, but the organization to deal with this branch of municipal work should not be limited to the mere laying and maintenance of pavements and their cleansing; it should extend to the planning of the lines and grades of the streets, the selection of the type of pavement for each street, a rational method of financing the cost of a street improvement, and also the proper placing and care of the underground structures, which do not appear in the show-window, but which, nevertheless, are an important adjunct to every street.

Mr. Trautwine.

JOHN C. TRAUTWINE, JR., ASSOC. AM. SOC. C. E.—Mr. Durham's discussion calls attention to what may be called two systems of stratification, in the matter of highway organization: (1) The vertical system, in which each of the several geographical divisions of a large city constitutes, in effect, a little sovereign state, with its own highway organization, independent of those of the other divisions; and (2) the horizontal system, in which a single highway organization presides over the highways of the entire city, including all its sub-divisions; as Pennsylvania's blanket of "new red shale" overlies the upturned edges of many much older formations.

Now, although Mr. Durham expressed his preference for the second, or horizontal system, the vertical system appears to obtain in

Mr. Trautwine.

New York City, where the Borough of Manhattan, the Borough of Queens, the Borough of the Bronx, and the Borough of "What-not," each constitutes apparently a little highway principality, with sovereign powers over its own affairs, and permitted to act (if it chooses) in imperial disregard of the arrangements and interests of the others; so that, conceivably, two adjoining boroughs, in an outburst of local patriotism, might so revise the alignments and grades of their highways that those of one borough should have no physical connection with those of the other.

Now, to paraphrase Sterne (who has been quoted in this discussion) the speaker submits that "we do these things better in Philadelphia." Mr. Connell will correct the speaker if he is wrong; but he is under the impression that Mr. Connell reigns supreme over the highway organization of that city, and that there are no highway chiefs of Manayunk, or of Chestnut Hill, or of Frankford, or of Southwark, empowered to regulate highway matters, in their several districts, without consulting him.

Philadelphia has the horizontal system of stratification; and this is in accord with the modern tendency to centralization, with its necessarily higher efficiency.

The programme for these meetings mentions State and Municipal Highway Organizations. The speaker ventures the prediction that, within 50 years, we shall have a National highway organization, administering the streets and highways of the entire nation, and of its cities, from whatever is then the national capital; and that, within a century, we shall have a World highway organization, similarly administering, from a central office, the streets and highways of civilization —with universal benefit on a scale now undreamed of.

The same will be true, of course, of matters like water supply and sewerage, now in general conducted (on the vertical system of stratification) by each city for itself; although Massachusetts (in the advance, as usual) has set a notable example in the formation of its Metropolitan Water and Sewerage Board, which regulates these matters for Boston and its neighboring communities, each of which formerly looked out for its own interests, mostly without reference to those of all the others.

Of course, it is not to be expected that the suggestion of a national and a world highway organization will be looked on with favor by incumbents of municipal offices which, under such organization, of course, would have to accept subordination in exchange for their present sovereignty, unless indeed from those who felt pretty sure of being called to the national or world chiefship.

Mr. Goldsmith.

WILLIAM GOLDSMITH, ASSOC. M. AM. SOC. C. E.—There is one detail in Mr. Connell's discussion which has proved of vital importance to the organization of the Highway Bureau in the Borough of Man-

Mr. Goldsmith.

hattan. This relates to patrol inspection. In past years civic organizations and private citizens have complained repeatedly about the poor condition of the pavements in Manhattan Borough, and particularly with reference to the length of time elapsing between the opening of a pavement and its final restoration. These complaints culminated in an investigation by the Commissioners of Accounts during 1906 and 1907. Their report showed:

First.—That there was no system which made it possible to follow up cuts made in pavements so that they could be quickly restored.

Second.—That the responsibility was not fixed, and the shifting of blame from one to another was not only possible, but was the case whenever difficulties arose.

In 1910, under Borough President McAneny, steps were immediately taken to remedy these conditions. The Bureau of Municipal Research, working in conjunction with the Bureau of Highways, inaugurated an inspection system, which, during the last 2 years, has worked admirably. Although this is a detail in highway organization, it is vital to success, and is worth while noting.

The city is divided into districts, for each of which there is a patrol inspector. His territory covers about 10 miles of pavement, there being about 450 miles of paved streets in Manhattan. It is the inspector's duty to report at least once a week regarding the general condition of the pavements, and to report promptly on all street openings, building operations, and encroachments for which permits are issued.

In order to give a clear idea of the inspection system referred to, take, for example, a plumber's street opening. The plumber must be licensed (pass an examination as to fitness, before the Board of Plumbing Examiners), and must execute a $1 000 bond with the city for the proper performance of his work. He comes to the Permit Division, which is under the direction of the Bureau of Highways. A technical man, called the Supervisor of Permits, is in charge of this Division, and keeps in direct touch with contemplated pavement work, sewers, or other constructions; sees that sub-surface corporations do their work in streets previous to resurfacing; that all departments are notified of contemplated constructions; and approves every permit before it is issued. The plumber makes a cash deposit covering the probable cost of pavement restoration. This payment includes an inspection and overhead charge (which amounts to approximately 50 cents per sq. yd.). He must also make a cash deposit of an equal amount, which is retained for 6 months, to insure the city against any settlement of the pavement, due to improper back-fill, or other poor workmanship.

As soon as a permit is issued, triplicate inspection forms are made out on a typewriter in the Permit Division. These forms provide space to give the inspector in the field all the information necessary for a

proper inspection of the work. These forms are called: (1) a "Preliminary"; (2) a "Tickler"; and (3) a "Final". Mr. Goldsmith.

The "preliminary" report is given to the inspector, whose duty it is to see that the conditions of the permit are complied with, to report thereon what work was done, and, by actual dimensions and sketch, show just how much pavement was disturbed, and the quantity to be restored and its exact location.

The "tickler" and "final" forms are filed in a cabinet provided for that purpose in the main office. When the "preliminary" report is received from the inspector, the "final" is sent to the pavement contractor, who honors it as an order from the city to restore the pavement. The contractor hands this "final" to his foreman, who takes it out on the work and makes the necessary repairs in amount and location as shown.

With these repair gangs there is another set of inspectors, called maintenance men, who are entirely independent of the patrol inspectors. The foreman of the repair gang hands this "final" report form to the maintenance inspector assigned to his work, and it is this inspector's duty to see that the pavement, of the exact amount and location shown on the inspection form, is repaired according to specifications. He then records the actual amount repaired and signs this "final" form in a space provided for that purpose. These maintenance inspectors are notified by a chief inspector, about 18 hours in advance, just where their work will be on the following day.

After the day's work is completed, the inspector fills out and signs the "final" reports, and mails them to the main office. In this way, an independent check is obtained, and collusion is almost impossible between the inspectors and contractors as to the area of pavement to be restored. The paving company then presents its bill for this restoration work to the city, and a clerk in the office, uses the "final" reports as a basis on which to approve the bills.

During 1913 an experiment on patrol inspection was tried, the object being to reduce the number of patrol inspectors and put them where the work was urgent. The territory north of 59th Street and west of Fifth Avenue, in Manhattan Borough, was patroled by one inspector in an automobile. Previously, this section had been patroled by twelve men. The difference in cost was:

12 Inspectors at. .	$1 200 = $14 400
as compared with:	
1 Inspector at. . .	1 800
1 Chauffeur at. .	1 200
Maintenance and depreciation of automobile	1 000
Total	4 000
Yearly difference, or saving.	$10 400

Mr. Goldsmith.

This covered a mileage of approximately 132 miles and gave a patrol inspection cost per annum of $30 + per mile, as compared with $109 + per mile by the old system, showing a saving of $79 per mile per annum, or a total of $10 400 per annum.

Although this scheme worked out well in the district where it was used, it probably would not be as effective in heavy traffic sections, where the territory covered would be limited on account of congestion and where the speed of the automobile would not be an advantage.

The inspection and follow-up system referred to, which includes a number of patrol inspectors and an independent number of maintenance inspectors, has the following advantages:

(1) It places individual responsibility on the inspector on the work, as the reports must be signed by him;
(2) It makes the shifting of responsibility impossible;
(3) Possible collusion between inspector and contractor is out of the question;
(4) Experience shows that better results are obtained.

The fourth statement is easily verified by a comparison between the present state of the streets in the Borough of Manhattan and their condition under the old system.

In a highway organization, the details of the inspection system are vital to a successful administration, because the success or failure of highway work depends on the field inspection. The speaker believes that the system outlined is feasible, covers all necessary requirements, and, if properly supervised, will get rid of many of the difficulties with which a city highway engineer must contend.

Mr. Ricker.

GEORGE A. RICKER, M. AM. SOC. C. E.—The speaker is glad of the opportunity to say a few words about the reorganization of the New York State Highway Department, and the methods that were followed in selecting the Division Engineers. When Commissioner Carlisle and the speaker undertook this reorganization there were only three regular Division Engineers on the work, and, as the new Highway Law commanded the redivision of the State into nine divisions, there were six vacancies to fill. It was somewhat troublesome to think of how to secure competent engineers for these divisions who, at the same time, would be good executives, for it must be borne in mind that these divisions are very large, each containing a mileage of roads as great as the whole of Massachusetts.

It was thought to be practicable to secure by civil service examination and appointment men who had the necessary personality, men with executive force and the ability to command. By permission of the State Civil Service Commission a plan of co-operation with the Highway Department was established in the preparation and conduct of an examination, which consisted of three parts. First, an oral

Mr. Ricker.

test (and there is point in its being placed first); second, two theses, one on the subject, "Essentials of Highway Construction," and the other on any large work in which the applicants had had experience; the third section consisted of a sworn statement of each man's experience.

There were about 160 applicants. One by one the men were called into the office of the Civil Service Commission on a given day, and two members of the Board of Consulting Engineers and the speaker sat with the Commission. An attempt was made to put the candidates at ease by the attitude of the examiners, and by asking them unimportant questions until any nervousness which they felt was overcome. After a few minutes' conversation the leading questions, calculated to bring out the characteristics of the candidate, were put. It was assumed that the candidates were ready with technical matter, but technical questions were avoided, as the examiners were quite sure that the men were well equipped along that line, and if not, that would be found out in the later tests.

The object of placing the oral test first, it will readily be seen, was because men of executive force and strong personality were needed. They might have all the technical knowledge in the world, all the education and experience necessary, but, if they could not control men, they would not make good Division Engineers. By this test it was possible to exclude from the examinations that would follow men who were lacking in necessary personality to make good executives. Some fifty or sixty men were selected, whom it was thought were very desirable, and they were instructed to enter the other tests. It should have been stated, by the way, that as each man left the room the examining board agreed on his mark before the next man was called.

The entire board read and criticized the theses, and, as a result of the complete examination, the Civil Service Commission presented a list from which six men were selected from among the first seven men: one from the Board of Water Supply, three from the Barge Canal organization, one from the Highway Department, and one who had had six years' experience in the Panama Canal work. These six men, with the three from the old organization, constitute the Division Engineers of the reorganized Department. All these men are members of this Society, and all are also graduates of recognized engineering schools, the several institutions represented being the Massachusetts Institute of Technology, Cornell, Rensselaer, Polytechnic, and Marietta College (Ohio).

Following this start in the reorganization, each of the Division Engineers has been supplied with an Assistant Division Engineer, the latter from promotions in the Department. An examination was held, following a plan similar to that outlined for the Division Engineers, and twelve men from the first thirteen were appointed, some divisions getting two men on account of their size and the magnitude

Mr. Ricker. of the work. These Assistant Division Engineers, technically known as Resident Engineers, were taken, with one exception, from the top of the list down. The one man passed, as in the case of the Division Engineers' list, was not passed on account of any political reasons. Politics had absolutely nothing to do with the selection of any of these men. They were chosen and appointed before any one of them knew that they were being considered, so that nobody had any chance to "see the Commissioner" or the speaker regarding them, and they had no opportunity to send anybody on their behalf if they had wanted to, and, as far as the speaker knows, none of them ever thought of doing such a thing. Thus it is seen that the reorganization is purely on a merit basis.

Arrangements are now being made for the selection of Assistant Engineers to place in charge of counties. The Division Engineers have recently met and discussed the list of available men presented by the recent promotion examination, and have agreed among themselves as to the disposition of these assistants throughout the State by counties.

An attempt is being made to establish something approaching a military organization, and the Division Engineer in complete charge of his division will be supported and sustained. Politics will have absolutely nothing to do with the work if it can be prevented, and it is thought that it can. Commissioner Carlisle, although not an engineer, has engineering sense, and in a marked degree possesses executive and administrative ability.

In January, 1914, there was established a system of weekly reports, which are really time sheets, so that every man in the Department reports to the Bureau head and Bureau heads send to the Department head a record of what every man is doing every day. Thus it is known where the men are, and what they are doing, and in that way one can readily keep track of the force.

FACTORS LIMITING THE SELECTION OF MATERIALS AND OF METHODS IN HIGHWAY CONSTRUCTION.

Mr. Tillson. GEORGE W. TILLSON, M. AM. SOC. C. E.—This subject is of great importance; it has been discussed for a great many years, and will be discussed for many years to come. The speaker has made the statement several times that in the preparation of plans for road and street work engineers were more behind than almost any class of constructive workers. That statement will have to be modified from time to time, as the subject is receiving so much discussion from year to year and from day to day.

It will be remembered that Mr. Green started out with a proposition that what was said in the discussion must be new. That is a

very difficult requirement, and, under it, the speaker feels that he cannot qualify, especially after listening to Mr. Green's discussion; he thinks that a man who could talk for ten minutes and say nothing but what was new to every member would be a wonder. If the speaker can suggest one idea that is new, he will be satisfied. The point he wants to make is that the ideas which govern roadway and street construction and the design of both must not be said once and then laid aside. In order to make inspectors and road supervisors entirely familiar with them, they must be reiterated, told over and over again, said in a new way, or said in the same way, until they know them as thoroughly as they know the alphabet. Mr. Tillson.

In the design of work of this kind, it seems that the first thing an engineer must do—and the whole situation will be discussed in as general a way as possible—is to make himself thoroughly familiar with the work that is before him. If an engineer is to design a bridge, if an architect is to design a building, the first thing to do is to find out what will be required of this bridge or this building. The first thing the engineer must do is to study the requirements of the road he is to build or the pavement he is to construct.

In doing that, he has a great many things to consider. That is brought out to a great extent by Mr. Green. The character of the traffic: Until the last few years no one has considered it necessary, or, if necessary, that it was worth while, to have a traffic census, either in city streets or country roads. No longer ago than December, 1912, at the Road Convention in Cincinnati, after an elaborate paper on "Traffic Census," and what was to be gained by it, a State engineer said, "Well, after all this traffic census, you have got to use your common sense." That is true. That is the very object of having the traffic census, so that common sense may be used intelligently.

Now, the traffic is not the only thing that must be studied. One must study where the road is to be laid, what its objects are, the character of the different traffics, and, another thing, not only the entire traffic, but how that traffic is to be applied.

The engineer of the Borough of Fulham, London, has calculated that, under a certain traffic which has been observed, a wood pavement will last for a certain term of years; and that, when a wood pavement is laid on any street, he can calculate its life in accordance with the traffic which is to be applied. That must be considered to a great extent in a way which the speaker will mention later.

Now, after one understands fully the requirements of the road, the next thing is to find out the character of the materials available for use. This part of the question was not nearly as important 30 or 40 years ago as it is to-day. At that time, stone in its various forms was practically the only material used in road or street construction. Now, there is not only stone, but brick, wood, and the bituminous

Mr. Tillson.

materials, the latter laid in all their various forms and composed of the different kinds of bitumens.

The engineer, in studying this phase, must consider first the character of the stone. He must know what the different kinds of stone will stand under the different kinds of traffic. The speaker was severely criticized once in college when he said—in considering the abstract question of foundations—that stone made the best foundations. His professor contended that the statement was absolutely wrong, because, under certain conditions, sand is just as good a foundation as stone. Now, under some conditions of traffic, a cheaper stone is just as good as a dearer, so that, though in a certain way one stone would be better abstractly, the other stone might be just as good concretely.

It is the same way with other materials. The engineer must understand brick and the different grades of brick; he must understand wood, what the different varieties of wood will do, what kind of treatment the wood requires; and then, when it comes to the bituminous pavements, he is uncertain at the present time. It does not make any difference where he goes, he will get different advice, different information. The information may be true, for the reason that different people are studying different kinds of bitumens, and they know more about the bitumens that they are studying than about any others, and while they are giving perfectly good and true information about their own, it seems to be contradictory to what was received before, because they did not understand the values of these other bitumens.

Now, let it be assumed that the engineer understands thoroughly the condition of his road, and all the different qualities of the materials, both in their crude state, and also how they can be mixed in order to produce satisfactory results.

The next thing is to make the application, and here there should be elaborated what was said about the traffic and the wearing out of the pavement in a certain length of time. Take, for instance, the assumption that a traffic of 60 000 000 tons will wear out a pavement, and the road will receive 2 000 000 tons of traffic per year. The logical deduction would be, then, that the pavement would last 30 years. Not necessarily; because there are certain materials in use which are affected chemically by climate and by the natural action of the atmosphere.

Now, as was stated by Mr. Green, wood and the bituminous pavements do require a certain amount of traffic in order to give the best results. So that, even if there exists a traffic which, theoretically and mathematically, would wear out the pavement in 30 years, this traffic may be so scattered that it would not be such as would be most economical and best for the pavement; and, on account of climatic conditions, it might be destroyed by disintegration and decay before it was worn out. Brick and stone are probably the only paving materials

Mr. Tillson.

now in use the life of which can be determined according to the foregoing principles, unless the traffic is so heavy that it will wear out the pavement before the materials decay or become disintegrated. The best illustration of this is in the use of wood. If these 60 000 000 tons of traffic will be applied to a pavement before the wood would naturally decay, there is no necessity for treating the wood with any material that will prevent it from decaying. That principle is recognized in Europe, where, in the great majority of cases, the wood will wear out before it will rot out, and it is only superficially treated. In Paris, where they use soft wood, and where the wear of the traffic in certain streets is such that the pavement will last only 7 or 8 years, they use what might be called no treatment; that is, the blocks are immersed for perhaps ½ hour in creosote oil and then laid in the streets.

Paris, last summer, was erecting a plant in which the blocks will receive a treatment of 10 or 12 lb. per cu. ft. That is not necessarily to keep the blocks from decaying, but to prevent them from swelling and causing the pavement to bulge. That is the main thing that they hope to gain by increasing the quantity of preservative to 10 or 12 lb. It can readily be seen that it would be wrong to use an elaborate form of treatment to prevent decay when the block itself will wear out before it would rot out.

In America, where there is not this intensive traffic, and where a pavement is expected to last longer, it is an entirely different proposition. Take a certain street, for instance, in Brooklyn, where wood block has been laid about 10 years. Practically no repairs have been made, and if the traffic continues as it has in the past 10 years—and being a residential street, it probably will—that pavement will not be worn out in 50 years from the time it was laid. So it will be seen how necessary it is to lay treated blocks under such traffic, so that they will last as long as they can, as far as decay is concerned; and for that reason it makes a difference whether the amount of traffic that will wear out a pavement is scattered over 4 or 5 years or 25 or 30 years.

There is just one little point more, which was referred to by Mr. Green and also to a certain extent, by Mr. Whinery. All these different principles that have been spoken of can be settled in the laboratory; but, if an engineer determines on granite, for instance, for a certain street, and writes to his client, who may be 400 or 500 miles away, and tells him of his decision, the client might write back and say there is not a granite quarry within 1 000 miles. The point to be recognized is the question of availability. That is of the utmost importance, and the speaker has often thought that, in the possibility, or rather the power, of Nature to furnish everything necessary for the development of the world, the development of civilization has been shown in the pavement line as much as in any other way.

Mr. Tillson.

In the Central West, where there is no rock suitable for pavement, where all outside materials can only be brought in at great expense, Nature has furnished a material—clay—from which can be, and is, manufactured a brick that gives satisfaction and is almost as durable as the best of stone itself.

In summation, let it be said that if an engineer, who has roads or street pavements to plan, has first a knowledge of the conditions which his pavements must meet, if he understands thoroughly the qualities of the available materials, and if with that knowledge he makes his application in accordance with sound common sense, taking into consideration the atmospheric conditions and the availability of materials, he will undoubtedly reach a conclusion that will give satisfactory results.

The following question has been asked: "What conditions would be considered, and would govern, in making a selection of asphalt blocks, brick, or bituminous concrete for a street, say, in Brooklyn?" This is easily answered, because, as a matter of fact, Brooklyn uses only one of the materials mentioned, *viz.*, asphalt blocks. Brick has not been used because it is expensive and makes a more noisy pavement than asphalt, so that the latter is more desired by the property owners. Asphalt blocks are generally selected in preference to asphalt where the grades are comparatively steep. The blocks are less slippery than sheet-asphalt, as they are made of coarser materials, and on account of the joints between the blocks. Brick would be selected for a street on which the traffic would be too heavy for asphalt block. The speaker has never used asphaltic concrete, and cannot give an opinion as to whether this material would give a better wearing surface than asphalt blocks.

Mr. Meeker.

ROBERT A. MEEKER, ESQ.*—The speaker cannot accept the theory of harmonic waves, said to be due to traffic, nor the beautiful system of harmony of the spheres, for, from practical experience, it has been learned in his Department that it is very necessary indeed to watch the output of the mixer carefully. The proportions of stone, of sand, and of asphalt may be all right, but the first run of the mixer will be too rich in asphalt, the middle of the run will be just right, and the latter part of the run will be too lean; consequently, one would have a pavement composed of, for example, 12%, 8%, and 4% of asphalt, all from the same mixer, notwithstanding that the stone was weighed and measured carefully, as was the asphalt, before either was put in the mixer.

This mechanical failure is often overlooked. It caused so much trouble that the speaker was led to make a careful investigation of the run of the mixer, and it was found that, in many cases, the asphalt concrete which had been condemned as not being properly mixed,

* State Highway Engineer of New Jersey.

owed its lack of uniformity, not to the workmen who were in charge (they had done their duty faithfully and carefully), but to the machine. Mr. Meeker.

In connection with this theory of harmonic waves, there was one very important point made by Mr. Washington which is worthy of more than passing notice, namely, the irregularities caused by improper rolling. The speaker has had considerable trouble in the past, even with water-bound macadam roads. When the causes of the so-called waves are carefully analyzed, it will be found that the trouble lies, not in the traffic, but in faulty construction. The first macadam roads built in the United States were rolled with heavy three-wheeled rollers. There never were any waves in those roads. Later, an endeavor was made to reduce the cost of construction, and, to that end, horse rollers were substituted for the heavy English steam rollers; still later, different types of steam rollers were used, and, last of all, the tandem roller was brought forward as the best. The speaker tried them, and had macadam roads with harmonic waves long before automobiles were used. The real reason for these waves, or hills and hollows, in the road, may be found in the method of construction. If the base is not thoroughly compacted, not thoroughly rolled, and not brought to an even and uniform surface, then, if those waves do not appear at once, they will develop eventually. When to this wavy base is applied bituminous concrete which is not uniform in composition, two sets of waves—two sets of hills and hollows—will appear, not due to traffic, but to careless construction.

Highway engineers should not try to dodge their responsibility for poor workmanship by charging it to motor vehicles or to the rhythm with which they travel over the highways, when the fault lies in the manner of construction. This must be carefully watched. Careless construction was one of the reasons for the failure of so many penetration roads. The speaker has had experience with penetration roads in which he was told that the distributing wagon had stood for a time at a certain point and that the hump of bitumen, seen on top of the road, was due to the fact that the controlling valves were leaking.

In one case, coming under the speaker's immediate observation, he knew that the wagon had not stopped within 100 ft. of that particular point; therefore, this explanation was evidently wrong; hence, a series of investigations was made, whereupon it was found that the percentage of voids in the road varied greatly. Where the road was comparatively dense, the bitumen appeared in humps on top of it and disappeared entirely at a depth of 2 in., and where hollows appeared it was found that the bitumen had penetrated in many cases to the depth of 7 in. The same quantity of bitumen per square yard of surface having been applied, there was consequently a recurrence of the fat and lean

Mr. Meeker. bituminous mixture encountered in the output of the mechanical mixer. A careful analysis of numerous faulty spots, in both broken-stone and bituminous pavements, has convinced the speaker that the varying percentage of voids is a fruitful cause of many so-called failures; in other words, a lack of homogeneity in the mass is the real cause of the wavy surfaces so often seen.

Mr. Beaty. R. E. BEATY, ASSOC. M. AM. SOC. C. E.—These remarks may not have a literal application to the discussion of "Factors limiting the selection of materials and of methods in highway construction", but, with regard to the use of wood paving blocks, the speaker is of the opinion that some mistaken ideas are abroad which should be corrected.

In European practice it has been customary to use a very light treatment in preparing blocks, that is, to treat them with 10 lb. of oil per cu. ft., or in some instances merely to dip them into the preservative.

The wood principally used in France is known as "Landes" pine; in England "Baltic deal" is used. An examination of some of these blocks shows very uniform wear, and that the wood very much resembles southern short-leaf, yellow pine, with the difference that the wood is much more nearly uniform in density and strength of fiber.

Tests made by the Borough of Manhattan, and by the Department of Forestry, of the United States Department of Agriculture, show very clearly that although some American pines very much resemble the timber used in France and England, they are of much less uniform quality. The characteristics of southern pines will be considered in more detail later.

In the speaker's opinion, it will be taking a grave risk to try to follow the European practice of using a light treatment of oil. This method will have the effect of leaving some of the blocks in the pavement untreated. This condition is indicated to some extent in foreign countries, where numbers of blocks have to be removed on account of rotting.

All the speaker's observations of experiments and—what is of more value—of the actual condition of 250 000 sq. yd. of blocks after treatment, in charges of from 400 to 500 sq. yd., has convinced him that, as the quantity of oil is decreased below 20 lb. per cu. ft., it becomes increasingly difficult to get either a uniform distribution of oil between the individual blocks making up the charge, or a satisfactory penetration into all the blocks. This difficulty can be overcome to some slight extent by the slow application of the oil, but this is not commercially desirable, for the reason that lengthening the time of treatment would often curtail the output of plants fully 33 per cent. Attempts at light treatment have been observed many times. In

Mr. Beaty.

one case, 16 000 sq. yd. were being treated with 16 lb. per cu. ft. The specific gravity of the oil used was 1.06 at 38° cent. At first a 16-lb. treatment was tried, but it was found necessary to increase this to 18 lb., because many of the blocks, when the lighter treatment was applied, showed a penetration of only ¼ in. from the surface. The inference is, that in injecting 16 lb. or less into the blocks, the duration of time the pressure is applied to the treatment cylinder is too short to allow the pressure to be raised to a height sufficient to cause oil to penetrate the denser and harder blocks before all the oil is used up. In experiments reported in December, 1912, on various samples tested for the Department of Public Works, Manhattan, it was shown that the quantity of oil taken up per cubic foot by the blocks, under a pressure of 150 lb. per sq. in., which pressure was necessary to inject an average of 20 lb., varied widely among the different species of southern yellow pine blocks making up the samples. Some blocks received the equivalent of 28 lb. per cu. ft., and others received only 12 lb. At less than 50 lb. cylinder pressure, 10 lb. can be injected. If thus treated, many blocks in a charge would receive practically no oil. This lack of uniformity in material, though not so marked in the "Landes" pine and "Baltic fir", indicates a cause for decay in individual blocks.

There is in very general use, by some wood block manufacturers, the term "Southern Yellow Pine" to describe the timber used in manufacturing their product. This nomenclature, as used in the 1913 *Proceedings* of the Association for Standardizing Paving Specifications, is intended to cover all the five or more varieties of pine found in the South, and it was so stated in the "discussion" at the time of their adoption. That the term is misleading, indefinite, and inaccurate is readily seen by a reference to Bulletin No. 13 of the Division of Forestry, of the United States Department of Agriculture, in which five species of pine, several of them occupying large and definite areas of the Southern States, are given, as follows:

"Long-leaf" pine (*"Pinus palustris"*, Miller);
"Cuban" pine (*"Pinus heterophylla"*);
"Short-leaf" pine (*"Pinus Echinata"*, Miller);
"Loblolly" pine (*"Pinus taeda"*, Linn); and
"Spruce" pine (*"Pinus glabia"*, Walt).

These species vary widely in physical characteristics, such as average percentage of resin, number of annual rings, weight per cubic foot, average percentage of heart wood, strength in compression of fiber parallel to the grain, etc. Two of these definite groups will be compared: the "Long-leaf" and the "Short-leaf" yellow pine. Tests

Mr. Beaty.

by the U. S. Department of Agriculture showed the following relative values:

	Long-leaf.	Short-leaf.
Strength in cross-breaking.....	10 900 lb.	9 230 lb.
Strength in compression (per square inch):		
Average lowest.....	5 650 "	4 800 "
Average highest.....	6 850 "	5 900 "

In summarizing the results of tests on various pines the Department expert states: "From these results, though slightly at variance, we are justified in concluding that Cuban and Long-leaf are nearly alike in strength and weight, and excel Loblolly and Short-leaf by about 20 per cent."

These values were checked by experimental tests, at Columbia University, on samples secured by the speaker for the Borough of Manhattan, to which reference has previously been made. The results of these tests are not given here as the tests were made to demonstrate the value of a requirement for a minimum number of annual rings in timber used in the manufacture of blocks. It is interesting to note, however, that the average strength of three samples of long-leaf was more than 10 000 lb. per sq. in. in compression, parallel to the fiber, and some samples of short-leaf were as low as 5 600 lb. per sq. in.

Other tests, made at this time by the Highway Department, indicated clearly that "short-leaf" pine, as compared with "long-leaf", has a greater range of expansion and contraction, and is more difficult to impregnate uniformly with preservative. Each of the species considered has its uses, but, as they often vary widely in price, as well as in physical characteristics (as has been shown), then, for the mutual protection of the bidder and the ultimate user, engineers should specify clearly the kind of timber to be supplied.

In the matter of the limitation mentioned by Mr. Tillson, the speaker heartily concurs. It would not be reasonable to conclude that, simply because "a block might possibly wear out before it would rot out", it would be wise to use a very light treatment.

It would be necessary to use a certain quantity of oil in order to protect the blocks against bulging or "buckling". The proposition to use untreated timber is also unwise, because it has been observed that, if certain varieties of pine, if untreated, are exposed to the weather, they will be destroyed by fungi and other destructive agents in less than 4 years.

Mr. Meeker's remarks with regard to proper proportioning and mixing are extremely important. Several engineers of the Bureau of Highways, Manhattan, have endeavored for the past 2 years to restrict the use of machine mixers to those of the "batch" type. It

has been noted that many "continuous" mixers furnish a mix which is often too "lean", and at other times practically devoid of stone. Mr. Beaty.

If continuous mixers are not considered safe for use on such structures as the Panama Canal, the Keokuk Dam, the New York Subway and the Aqueduct work, their use should not be permitted for mixing concrete for use in foundation for pavements designed for heavy traffic.

WILLIAM M. KINNEY, JUN. AM. SOC. C. E.—Referring to concrete pavements in which there appears to be some pulverizing action under the bituminous carpet, the speaker has made quite a number of investigations of pavements of this type and, in the few cases where such condition exists, has found that the surface of the pavement, prior to the application of the bituminous carpet, was of poor quality, either because of the use of poor aggregate, or because the surface of the concrete had been frosted. Mr. Kinney.

In floating concrete made from an aggregate in which there is an objectionable quantity of dirt or loam, this unsatisfactory fine material is brought to the top of the concrete and makes a surface which is of poor strength and to which another material does not readily bond. A skin on the concrete thus formed might show the pulverizing action to which Mr. Crosby has referred.

When the concrete has been frosted prior to the application of the bituminous top, practically the same result would be expected, as the thin layer loosened from the concrete by the freezing action would pulverize rapidly under travel.

When properly made concrete is covered with a bituminous carpet, and this carpet later peels off, there is usually very little material such as sand, gravel, or mortar clinging to the bituminous material.

It would be interesting to know the location of the roads to which Mr. Crosby refers, and to ascertain whether a report on the character of the aggregate and time of doing the work is available.

WILLIAM GOLDSMITH, ASSOC. M. AM. SOC. C. E.—Speaking about harmonics and what Mr. Washington has said, the speaker would like to relate one little incident which happened on Second Avenue, in New York City, which brings out that point rather clearly. Mr. Goldsmith.

From 1st to 23d Streets, on Second Avenue, experimental pavements have been laid and on one stretch, between 15th and 17th Streets, the pavement is of asphalt block. This section is in itself an experiment, different qualities of blocks being used within the area. One part of it is laid with soft blocks having a large percentage of bitumen. Other sections are laid with harder blocks.

About a year after the pavement was opened to traffic, a number of depressions and holes appeared, and the wave effect which has been mentioned was also evident. It became necessary to replace these

Mr. Goldsmith.

defective parts, and in ripping up the old blocks, a curious condition was found. The asphalt blocks which were lined up perpendicular to the curb had taken a semicircular form; they had moved up on one another under the heavy traffic, so that waves were formed. Originally, the blocks were 5 in. wide, 12 in. long, and 3 in. deep. When removed their depth was found to vary from a minimum of 1 in. to a maximum of about 6½ in. The width and length had correspondingly increased or diminished, showing that there was little if any wear of the material, but that a distortion of the blocks had taken place. This showed conclusively that the asphalt moved or crept up and worked into semicircular shape, because the blocks were soft, and not on account of rolling. Adjoining these particular blocks were some of a harder nature which retained their shape, thickness, and alignment.

Approximately every 6 ft., and perpendicular to the curb, steel plates were embedded in the concrete foundation, extending up into the asphalt block joints. The object of these plates was to prevent the creeping and distortion of the blocks, which was anticipated. The plates, however, took the same semicircular shape with the blocks, the pressure evidently being great enough to detach them from the concrete in which they were embedded.

There was no grade on that part of the street where these blocks were laid. The traffic, both light and heavy, moved in the direction of the curves, and the latter had a middle ordinate of about 7 ft., the chord being about 20 ft.

This incident seems to show that in this case the wavy effect was due to the softness of the material under heavy traffic, and not to any other cause.

There is another point, which has not been spoken of, but is of great importance. It is the factors which limit the selection of pavement to be used in the railroad area in city streets—asphalt, wood block, granite, or other material used in city streets. Many streets have car tracks in the center. The question always arises, shall the same pavement that is used in the roadway be placed within the railroad area?

According to the usual railroad laws and charter requirements, the pavement between the railroad tracks and for 2 ft. on each side of them, is maintained by the railroad company, but must be constructed in accordance with specifications prepared by the city engineer.

Investigations in New York City have shown more depressions and other defects on pavements between the tracks and near them, than at other places. The question, therefore, naturally arises, which is the best pavement to place in the railroad area? Asphalt, wood block, or granite?

The consensus of opinion in Manhattan Borough seems to be that the improved granite block is the most satisfactory. It has some dis-

advantages, however, on account of the ties which come in between the slot rail and track, which make it necessary to chip the granite blocks to make them fit well between these cross-ties. Mr. Goldsmith.

The joints, in Manhattan Borough, are made with paving pitch and sand. The speaker is informed that the street railroad companies in Brooklyn have used cement grout almost entirely during the past 8 or 10 years, and very successfully.

This subject is brought up with the hope that some one will discuss it and give his experience with relation to pavements in the railroad area.

GEORGE A. RICKER, M. AM. SOC. C. E.—In reference to this subject of materials some curious things have happened in the New York State Highway Department, as disclosed by recent investigations, and steps are being taken to try and correct mistakes that have been made. Mr. Ricker.

Roads were designed by some of the engineers who had never seen the territory in which the road was located. Specifications were applied to sections of which the engineers were totally ignorant of conditions. The speaker found places where solid rock was being excavated, and the road replacing it made of concrete, and where bituminous roads were built on blow sand foundations. At present the Division Engineers are required to send in, with their plans of roads to be improved, a report of their personal inspection after walking over them.

The Department has also instituted a survey of the State to locate available materials. One of the Assistant Engineers, who is somewhat of a geologist, and has been engaged in the Testing Bureau for some years, has been assigned to the work of examining materials in all parts of the State, and a chart is being compiled as a record of his examination.

D. B. GOODSELL, ASSOC. M. AM. SOC. C. E.—The speaker cannot say much about "harmonic waves" in asphalt or bituminous pavements, but readily agrees with what Mr. Washington has said regarding Mr. Crompton's ideas as to rolling. He believes that waves such as mentioned by Mr. Crompton might occur in some hard homogeneous material, but, with one as plastic as a bituminous pavement, such waves are likely to be due to two causes: lack of cross-rolling, and lack of homogeneity of the material. Most highway engineers are familiar with the effect of cross-rolling, and the speaker believes that, if roads generally were rolled crossways, as well as longitudinally, the regular waves would not occur as frequently. Mr. Goodsell.

No doubt the uniformity of the material, or in other words, the number of voids in it, has a very great influence on the evenness of wear; and the secret of obtaining a good road, other things being equal, seems to be the even distribution of voids throughout the material.

Mr. Goodsell. Attention is called to the measurements of wear of pitch-macadam pavement made by Mr. John Brodie, City Engineer of Liverpool, which seems to be the only instance of systematic measurement of wear under known tonnage of traffic. Some method such as he uses seems to be desirable for the determination of the relative life of the various kinds of hard pavement, including asphalt block. The speaker is not informed of any measurements which show the relative wear of asphalt-block pavements, and believes that this subject is an interesting field for investigation.

Mr. Durham. H. W. DURHAM, M. AM. SOC. C. E.—Reference has been made to stone block pavements in the car tracks, and to the different methods of filling joints. The speaker thinks that one important point in New York City practice was not brought out as clearly as possible. It explains very largely the difference between the practice in the Boroughs of Brooklyn and The Bronx and that adopted for Manhattan, and is mostly due to the radical difference in the types of track construction. In Manhattan an underground current-conductor with central slot between the rails is used almost entirely. In all the other Boroughs current is taken from an overhead wire, necessitating no special work in the track. The Manhattan construction requires the possibility of very frequent access to the substructure, for repairs either to the current-conductor system or the cast-iron yokes carrying the track. Therefore, it has been found more desirable to use a type of pavement which can be easily removed and promptly restored after repairs are made.

The use of a cement grout as a filler gives an excellent surface between the rails, as may be seen on some of the Brooklyn and Bronx streets; but if this were used in the Manhattan track construction it would render very difficult the making of any openings for repairs to the numerous hand and manhole boxes and other sub-surface structures, and it would also be difficult to obtain proper setting of the grout filler after repairs were made. This largely explains the difference in practice.

EQUIPMENT AND METHODS OF MAINTAINING BITUMINOUS SURFACES AND BITUMINOUS PAVEMENTS.

Mr. Spencer. HERBERT SPENCER, ASSOC. M. AM. SOC. C. E.—Any discussion of a subject such as the equipment and methods for maintaining bituminous surfaces and bituminous pavements must, of necessity, be limited by the length of time such surfaces have been in existence, and should properly include: (1) classification of the surfaces and pavements required to be maintained; (2) methods and material used in their construction, together with the causes responsible for their failure; and (3) equipment and methods required for their maintenance. The subject being of such importance, and having such possibilities of detail,

Mr. Spencer.

the writer is of the opinion that a summary of these headings is all that should properly be attempted in a limited discussion of this nature. It must also be remembered that bituminous surfaces and pavements of various kinds having a large mileage, have ended their period of usefulness, and their maintenance now becomes a matter of first importance and requires the development of machinery and methods for their economical upkeep. These can come only from actual experience, and the lines along which such development should follow is all that can be attempted at present.

During the past 5 years many types of bituminous surfaces and pavements have been placed on the public streets and highways. Some of these have attained sufficient merit in the public estimation to warrant their continuation, and others have shown such faults in their original design and construction that their further development was not considered economical or wise. Without doubt, new types of bituminous surfaces and pavements will be exploited with the growth of highway work, but it is felt that these cannot deviate very much from the existing types, which are defined by the Special Committee on Bituminous Materials for Road Construction as consisting of superficial coats of bituminous material with or without the addition of stone or slag chips, gravel, sand, or material of similar character. This definition may include: (*a*) treatment of gravel or stone roads with cold bituminous material; (*b*) treatment with hot bituminous material; or (*c*) treatment of a Portland cement concrete base with either hot or cold bituminous material.

The Special Committee on Bituminous Materials for Road Construction defines a bituminous pavement as "One composed of stone, gravel, sand, shell, or slag, or combinations thereof, and bituminous materials incorporated together by mixing methods." This definition may include: bituminous concrete, laid either hot or cold; bituminous macadam (penetration method); bituminous mortars, consisting of bituminous cement and fine material aggregate, such as rock asphalt, and laid either hot or cold; sheet-asphalt, asphalt block, and similar pavements

The maintenance of bituminous surfaces and bituminous pavements is measured largely by the methods and materials used in their original construction. Although it is not considered necessary to enter into a discussion here of the specifications for any of the types just mentioned, the generally accepted limitations of methods of construction may be summarized as an index to the extent of maintenance.

For bituminous surfaces, the thorough sweeping of the base is of great importance for applications of hot bituminous materials, and should be resorted to for cold applications wherever an extremely dusty condition of the surface is found. The bituminous materials used range from asphalt oils and tars to the heavier products, of like char-

Mr. Spencer.

acteristics, requiring heat for their application. Of importance is the selection of the cover. For the hot applications, coarse sand or grits, preferably washed, are commonly used for automobile traffic; but, for steep grades and horse-drawn traffic, stone screenings are better. The items, therefore, influencing the success or failure of bituminous surfaces include the preparation of the base, the selection of the bituminous material, the selection of the cover, and, of equal importance, the machinery to be used in the application of the bituminous material. The treatment of cement concrete surfaces with bituminous material is of too recent origin to warrant an opinion of probable causes of failure, but may be due to any of the following: (1) base floated to a smooth surface, precluding possibility of any bond with bituminous material; (2) bituminous material lacks necessary characteristics to enable it to adhere to concrete; (3) base too hard and surface too thin to resist impact of horse-drawn traffic and raveling of surface results.

The danger of failure of bituminous pavements is lessened when care is used in the preparation of specifications and intelligence is shown in the inspection of the work. When failures do occur, they can generally be traced to unsuitable materials, poor foundations, improper machinery, or inferior workmanship. Bituminous concrete mixtures depend to a large extent on their structural stability, which is determined by their density, and by the continuous adhesion of the bitumen-covered particles under traffic, and violation of such well-known principles as grading of the mineral aggregate, consistency of bitumen used, or temperature of mixture and manner of laying, will lead to failure. For bituminous macadam pavements constructed under the penetration method, the quality of the stone, the proper sizing of the stone for each successive course, and the consistency of the bitumen used often determine the success of the pavement. These features were discussed by the writer in the 1912 Road Meeting of the Society.* It is not considered advisable to enter into a description of the causes of failure of sheet-asphalt, asphalt block, and similar pavements at this time, as this subject is fully covered in the discussions of Societies giving particular attention to these classes of pavements.

Bituminous surfaces originally treated with cold bituminous material may be renewed at slight cost. The extent of sweeping such surfaces is governed by the area and character of the existing cover on the road. If all loose dirt is swept from the original surface, and the bituminous material is covered with clean sand or screenings of a character not readily ground up by the traffic, then a re-treatment without the necessity of sweeping may safely be attempted. Roads properly cleaned, oiled, and sanded should leave a coating of bituminous material

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 615.

to which the fresh material can readily attach itself. The quantity need not exceed ⅜ gal. per sq. yd., and if sand is required, not more than 10 lb. per sq. yd. should be used, or a mushy, soft condition will follow. The bituminous material should be of such consistency that it can be readily applied by a pressure distributor, and should contain a minimum of material likely to lubricate the stone base. Where more than one application per season is required, the road should be treated in the fall, in order to assist as much as possible in maintaining the surface through the winter. Mr. Spencer.

The most successful hot oil or blanket treatment, in the writer's opinion, is that which has been done in Massachusetts; and, on many miles of roads which he has been over in that State the problem of maintenance has been solved successfully. Mr. Farrington has carefully gone into the methods of maintaining this type of surfacing, and detailed descriptions, extending over a period of 4 years and given in previous publications of this Society by Messrs. A. W. Dean, F. C. Pillsbury, and J. A. Johnston, should serve as a model in those communities which really desire economical maintenance on roads subjected to heavy automobile traffic. For roads treated by the hot blanket method and showing the holes due to settlement of foundation, heaving by frost action, or wearing away, caused by lack of adherence to the base, the earlier such defects are repaired the longer will be the life of the treatment. After 2 years' service of a treatment of this nature, during which time not more than one-third of the surface should be in need of repairs, it becomes a question of the advisability of re-treating the entire surface or of tearing it up and resurfacing with a more permanent pavement. For the repair of minor holes, a well organized gang can readily keep a stretch of road in perfect condition at a moderate outlay for plant and materials. Such a repair outfit should have a portable kettle, for heating the bituminous material, and a compartment for keeping dry the grits or screenings. The hole to be repaired should be swept clean and painted with hot bituminous material of the same consistency as that used in the original treatment, and then filled with grits or screenings to the level of the surrounding surface. This should then be grouted with bituminous material and covered with a light layer of stone chips or gravel. Where practicable, the patches should be rolled, and should be carefully watched to see that the traffic does not tear them out before they properly set. Another method of repairing such bituminous surfaces successfully is by mixing the aggregate and bituminous material away from the site of the road and depositing them in the hole to be repaired. This should be tamped, sanded, and thrown open to traffic. The writer believes this method leads to more uniform results.

Bituminous Pavements.—The maintenance of the older types of bituminous pavements has been sufficiently studied to need no elabora-

Mr. Spencer.

tion here. This refers to bituminous concrete, sheet-asphalt, asphalt block, and rock asphalt pavements. The more recent bituminous macadam pavements constructed under the penetration method in many cases show the need of immediate repairs. A study of the causes responsible for such failure should be made with a view of obviating these defects in the original construction. The writer, however, does not at all agree that the penetration method is the total failure that some authorities would have us believe, but is convinced, on the contrary, that for certain kinds of traffic this type of pavement is good enough. This conviction is based on the features of low first cost, length of service, ease of repair, and moderate charge for plant rental with which to apply the bituminous materials properly. Penetration pavements have now been down for a period extending through five summers and winters, have had no repairs spent on them, and are still in perfect condition. Where failures have occurred they can generally be traced to some defect in the original construction. The main causes of such failures are: (1) improper foundation; (2) improper sizes of mineral aggregate; (3) sealing of top course before applying bituminous material; (4) bituminous material of wrong consistency; and (5) uneven application of the materials. The various ways that failures occur in work of this nature are shown on the surface by: (*a*) wavy condition, showing either an unequal distribution of bituminous material or lack of bond to the underlying stone; (*b*) depressions in the surface, due to settlement of the foundation; (*c*) raveling, due to the bituminous material not adhering to the stone; (*d*) surplus of bituminous material on the surface, due to the difficulty of penetrating the stone, combined with improper consistency. For patching holes in a penetration road it is best to clean it thoroughly, scarify the surface, and add sufficient stone to bring the top course to the level of the surrounding road. The heated bituminous material is then applied, and stone of the next smaller size is rammed into the interstices. Generally, only one application is required, and care should be taken that the patch is at the same level as the surface of the road. Where there is an extreme wavy condition, it would probably be found more advisable to scarify the entire surface, adding sufficient stone, if necessary, and treating it with a light application of bituminous material followed with screenings and thorough rolling. Where raveling has taken place, a blanket treatment of bituminous material, applied under pressure, will often seal the road, without the necessity of scarifying.

Bituminous concrete pavements laid cold (including bituminous mortar) are ordinarily maintained with material prepared at some central point and shipped to its destination. This may be used to repair holes or to spread over the surface to form a new roadway.

Mr. Spencer.

Equipment.—For the application of bituminous material, by far the most successful method is by the pressure distributor. This may be horse-drawn, operating a small pump by a sprocket chain, or the pump may be driven by a gas engine in the rear of the wagon; but the most economical is the auto-driven sprayer. The speed can be regulated to spread any quantity required in a uniform spray, and under uniform pressure. For the blanket treatment, there has recently been placed on the market a machine designed to apply heated materials under pressure. This is considered the most advanced and improved method of applying heated material, and its use should be encouraged wherever possible. The outfit consists of a double-shell, asbestos-lined tank, holding from 750 to 1 000 gal., and containing 1½-in. heater pipes. A boiler, equipped to burn either coal or fuel oil, is carried on the rear. This furnishes steam to heat the bituminous material in the tank and to operate an air compressor. The bituminous material is forced through the outlet nozzles under the pressure desired, the quantity being gauged by the speed of the truck and the size of the outlets. This machine can apply the heavier material used in the construction and maintenance of bituminous pavements under the penetration method, and can readily apply the seal coat on bituminous concrete pavements. Where long stretches of road are in need of repairs, the auto-truck sprayer will be found the most economical, and where communities do not care to invest in the costly machines of this nature their services can be contracted for, on a gallon or yardage basis, from the companies operating them.

Indirectly related to the question of maintenance is the uniformity of the bituminous material to be used. There have been discussions at various times relating to the physical and chemical requirements of bituminous materials, and specifications, designed to limit and control their manufacture, have been drawn. Speaking only in reference to petroleum asphalts, with which the writer is more familiar, a few of the features governing the manufacture of the products under given specifications will be cited as illustrating some of the difficulties attending its preparation. In the first place, for a given grade of crude oil, a uniform product should result from the manufacturers' plant. On the other hand, elaborate tests may be interesting, as a matter of record and to classify the asphalt used in any given piece of construction, but when the manufacturer is asked to meet a variety of tests, necessitating a change in his process, a hardship is imposed on him, with no betterment of the resulting product.

The manufacturer who uses stills in the preparation of his material is governed largely by three fundamental conditions: (*a*) the character of the base material he is refining; (*b*) the temperature of distillation; and (*c*) the time of distillation. For a given crude supply, which may be considered satisfactory for the preparation of asphalt, it will be

Mr. Spencer.

seen that the resulting product is dependent largely on the temperature and the time of distillation. In many cases any change in one to meet a given test will affect seriously more important and necessary tests. As an illustration may be mentioned the fixed carbon requirement in certain specifications. It is agreed, on excellent authority, that the fixed carbon in an asphalt is the product found by dividing the fixed carbon in the crude material by the yield. Therefore a blanket clause in specifications limiting the percentage of fixed carbon, without taking into consideration the crude material which is being run, imposes a condition which the manufacturer is powerless to meet. He cannot control the minimum of fixed carbon, which is governed entirely by the yield and percentage in the crude, and a certain leeway should be given him for the maximum, to allow for errors in the test, imperfections in the process, and causes over which he has no control. Temperatures may control this maximum; but, in making a product for the highest class of paving work, there is no incentive or desire on the part of the manufacturer to injure the product in any way possible, and he would have no object in running at a temperature other than that which will produce the best material.

Engineers are prone to adopt technical specifications for materials used by other communities without investigating their merits as applied to their own work. Although this may be taken as a compliment to the originators of such specifications, in many cases it is done through a lack of knowledge of the materials to be used, whereas the unbiased judgment of those qualified to speak, with an eye to the considerations of cost and durability, will aid many engineers in the intelligent preparation of specifications.

The opinions of engineers assembled to discuss almost any form of construction and tests on most grades of materials will represent the most up-to-date and best thought, and engineers cannot go far astray in adopting such specifications, provided they have been tried and in actual use. Therefore national societies have a duty to perform in perfecting specifications for paving materials which are to be used generally throughout the country, and care should be taken that such specifications contain only those items which will insure a satisfactory product for the work to be done and not impose conditions impossible to fulfill with the materials available.

Mr. Boorman.

T. Hugh Boorman, Esq.—In the discussion 2 years ago the speaker stated that Nelson P. Lewis, M. Am. Soc. C. E., Chief Engineer of the Board of Estimate and Apportionment of the City of New York, had considered that rock-asphalt pavements were probably the best that had been laid. George W. Tillson, M. Am. Soc. C. E., objected to it because he considered the maintenance charges on it excessive. The speaker, therefore, begs to state that rock-asphalt comprimé has been

Mr. Boorman.

laid in the United States in New York, Brooklyn, Long Island City, and Rochester, in New York State; Elizabeth and Perth Amboy, in New Jersey; Boston, Mass.; New Haven, Conn.; Philadelphia, Pa.; and New Orleans, La.

The first comprimé work was laid in Union Square, New York, in 1872. In August, 1897, 112th Street, from Fifth to Lenox Avenues was laid, and the city records show that in 1912 the cost of repairs on this street was only 6 cents per sq. yd.; and 101st Street, from Lexington Avenue to Park Avenue, paved in July, 1896, with Mons and Sicilian rock, bears no cost for repairs from 1910 to 1913. Such durability seems to be unparalleled in the history of street construction. On Dyckman Street, from Kingsbridge Road to the tracks of the New York Central and Hudson River Railroad, 8 000 sq. yd. of Seyssel and Sicilian rock asphalt were laid in the late fall of 1897, and the cost of maintenance for the 4 years, 1910 to 1913, inclusive, was 3 cents per sq. yd., or less than 1 cent per sq. yd. per year. In 1901, between Park and Lexington Avenues, 35th and 36th Streets were paved with Seyssel and Sicilian rock asphalt; on 36th Street no repairs were necessary for the 4 years, 1910-13. In the same year 13th Street, from Second to Third Avenues, was paved with Sicilian and Mons rock on an old stone foundation, and is charged with 14 cents per sq. yd. for 4 years' maintenance. In 1897, 106th Street, from Broadway to Riverside Drive was paved with Sicilian and Mons rock, and shows cost for repairs of 17 cents per sq. yd. for 4 years, a trifle more than 4 cents per year.

To come to more recent times, it was decided in 1912 by the Department of Highways, under the advice of E. P. Goodrich, M. Am. Soc. C. E., Consulting Engineer to the President of the Borough of Manhattan, to lay a series of test pavements on Second Avenue, from Houston to 23d Streets. Rock asphalt comprimé, rock-asphalt blocks, and Sicilian rock comprimé were laid between 19th and 21st Streets, and on inspection, in January, 1914, these two blocks were found to be in good condition, the only imperfection being in the work adjoining the car tracks. This is not to be wondered at, as all rock asphalt experts, such as Malo, Delano, Walsh of Amsterdam, Bassett of London, and almost all engineers in Europe have decided that granite or other blocks should be laid longitudinally beside car tracks. The speaker recommends scoria blocks. The most noticeable of all the experimental pavements on Second Avenue is that of rock asphalt compressed blocks, between 9th and 11th Streets. These blocks were manufactured, at the Staten Island Works of the Sicilian Asphalt Paving Company, in an ordinary German brick machine, and did not receive the perfect compression obtained by the Val de Travers Asphalte Paving Company in their works at Marseilles, Seyssel, Cairo, Egypt, and other places. However, the rock being pure crude rock asphalt powder before being

Mr. Boorman.

pressed, simply spread under heavy traffic, and became virtually a monolithic sheet of rock asphalt, and it affords to-day as perfect a specimen of rock asphalt pavement as can be seen in any country.

Mr. Delano, on the occasion of his visit to New York in November, 1913, stated that the City of Paris had recently signed contracts for replacing wood blocks, stone sets, and macadam with 700 000 sq. m. of rock asphalt pavement, to be laid during the next 5 years. Attention is also called to the fact that, some years ago, Thomas Street, from Broadway to Church Street, and Trimble Place, from Thomas to Duane Streets, both private streets owned by fifty associates, were paved with Neuchatel Rock Asphalte Pavés and coated with an asphalt rubber surface coat, only $\frac{3}{8}$ in. thick, which has stood the heavy traffic of those busy thoroughfares for several years.

The speaker can prove that rock asphalt is the most valuable pavement in the United States. This is stated especially because so many engineers doubt that any European rock asphalt, such as laid in London, Paris, and Berlin, has ever been laid in the United States. The speaker is sorry that, owing to the short time allotted to him, he will not have the opportunity to say a little about its history in America.

The reason this subject of the practicability of the use of European Rock Asphalte is so much more important than when the discussion before the Society was held in 1912, is that the tariff on asphalt has been removed, and Rock Asphalte powder can now be purchased at a cost of $3 per ton less than in 1913, making a difference of 25 cents per sq. yd. in the cost of the surface. Municipal plants can be supplied with the material, all ready for heating and compressing on the street, and no additional outlay for machinery is necessary. Both the Borough of Manhattan, which is now completing its new municipal asphalt plant, and the City of Philadelphia are considering the advisability of doing their own repairs to rock asphalt streets.

Mr. Sharples.

PHILIP P. SHARPLES, ESQ.*—One or two points brought up in the discussion were not entered into very fully. For a number of years the speaker has been very much interested in studying the effect of oil on tar-bound macadam pavements. In considering the subject, country road practice and city or town practice must be sharply differentiated.

In building country roads, such as those described by Mr. Farrington, it has been the practice in many cases to construct a tar-bound macadam road, and coat it with one of the heavy asphaltic oils or light asphalts put on hot. This practice has given excellent results in many cases, and has been established as a standard specification in some States, notably in Connecticut. Some very good work has been done in this way.

*Chf. Chemist, Barrett Mfg. Co., Boston, Mass.

Mr. Sharples.

In carrying out work under a specification of this kind, it is very important that the grade of oil or oil asphalt be so heavy that it will not penetrate the tar-bound macadam, but will stay on top as a blanket layer. An oil light enough to penetrate the tar-bound road is sure to give bad results. The speaker knows of a number of roads of this type, which were well built and then treated with a light oil, while still presenting a porous top. They disintegrated completely within a year when subjected to heavy horse-drawn traffic, although neighboring sections sealed with tar products remained in good condition. If, however, a proper grade of asphaltic oil is used, this disintegration will not occur.

Under city or town traffic conditions, the tendency of an oil-asphalt top over a tar-bound macadam is to mush up and become soft under horse-drawn traffic in wet weather, due to the emulsifying effect of the water and organic material which collects on the asphalt top. When these conditions are to be provided for, it is important, so far as present experience indicates, to use only tar seal coats on top of the tar-bound macadam. The refined tars used for seal coats are preferably somewhat softer than the tar used in the tar-bound macadam, but the subsequent treatment and care of the road modifies somewhat the character of the seal coat required.

For maintenance within city and town limits, where the horse-drawn traffic is considerable, it has been found that a specially prepared tar, which can be applied cold, gives much better results than the heavier tar materials put on hot.

There are records of streets, in the vicinity of Boston, which carry more than 4 000 vehicles per day, which have been kept in good shape since 1908 with an annual maintenance cost of about 3 or 4 cents per sq. yd., with prepared tar applied cold.

Consider the light dust-laying oils and their effect on tar-bound macadam. It is a problem which affects city and town conditions. In country practice, the conditions do not arise where an oil of this type is necessary. On city and town streets, a troublesome dust often collects, which the ordinary seal coat of tar or heavy asphalt does not keep down. In applying a light oil over a tar-bound macadam to keep down this superficial dust, it is essential to comply with certain conditions if the tar-bound macadam is not to be ruined. It is the utmost folly to put a light oil on a tar-bound macadam; if there is the least chance for the oil to penetrate the macadam, the results are sure to be disastrous. The tar-bound macadam will be disintegrated. A light oil has two effects on the tar-bound macadam. It has a chemical effect on the tar which causes its disintegration and makes it lose its binding force. It also has a physical effect on the macadam structure. The oil is a lubricant; and if there is any stone loose enough to move in the tar macadam, the light oil accelerates the movement,

Mr. Sharples.

and a hole is sure to develop. This dual action of the light oil can be observed in many large cities at the present time, and many streets may be seen which have been built with tar-bound macadam, the life of which has been gradually shortened by the use of light oil.

The effects of the light oil can be minimized if the tar-bound macadam is thoroughly sealed, either through an excess of bituminous material in the first place, or by subsequent applications of refined tar. Certain precautions must be taken also in applying the oil. An excess of oil should never be used, and it should be applied to the surface only in sufficient quantity to take up the loose dust which is found there. A very small fraction of a gallon is sufficient. If more than this is applied, the oil gradually sinks into the tar-bound macadam and in the end will rot it.

Wherever a light oil treatment is used on a city or town street for dust-laying purposes, it is quite essential to revivify the surface of a tar-bound macadam from time to time by the application of a tar seal coat. For this purpose nothing seems to be better than a prepared tar of such consistency that it can be applied cold. Only a very small quantity is required, usually not more than ¼ gal. per sq. yd. per annum. If these applications are put on intelligently, and if patching is intelligently attended to, a tar-bound macadam will give good service, even in the face of light oil applications.

STORAGE TO BE PROVIDED IN IMPOUNDING RESERVOIRS FOR MUNICIPAL WATER SUPPLY.

Discussion.*

BY L. J. LE CONTE, M. AM. SOC. C. E.

Mr. Le Conte.

L. J. LE CONTE, M. AM. SOC. C. E. (by letter).—The writer is much pleased with the results of the investigation given by the author. In May, 1901, he wrote a paper on this interesting subject for the American Water Works Association. This paper was intended only as a rough general guide to aid the judgment of engineers who were in trouble. Since that time he has been called on repeatedly to explain. Accordingly, he gives the following specific case:

Let x = average rainfall for the 3 dryest years on record.

The average run-off $= \frac{x}{2}$

The average catch $= \frac{x}{2} \times \frac{1}{4} = \frac{x}{8}$.

Assume x $= 40$ in.

Then average catch $= \frac{40}{8} = 5$ in. per annum.

$5 \times 17\,400\,000$ gal. $= 87\,000\,000$ gal. per sq. mile; continued for 3 years $= 260\,000\,000$ gal. per sq. mile.

Where local experience indicates that it takes 2.5 sq. miles of water-shed to furnish 1 000 000 gal. per day in a long dry spell, then $260 \times 2.5 = 650\,000\,000$ gal. storage, which is necessary to insure a supply of 1 000 000 gal. per day in a long dry spell.

* Continued from February, 1914, *Proceedings*.

Mr. Le Conte.

Referring to Fig. 32, the writer is pleased to note a practical corroboration of this result. The Croton storage is given as 101 300 000 000 gal., and the water-shed as 360 sq. miles. This makes a storage of 290 000 000 gal. per sq. mile, for New York. The Spring Valley Reservoirs, at San Francisco, Cal., have 30 000 000 000 gal. storage for 30 sq. miles of water-shed, or, 1 000 000 000 gal. storage per sq. mile.

Then, $\frac{1\,000}{290} = 3.45$ times as much storage as is required in New York. Why? Simply because at San Francisco it takes 5 sq. miles. of water-shed to furnish 1 000 000 gal. per day, whereas in New York it only requires 1.5 sq. miles to deliver that quantity. In the New York case then, $260 \times 1.5 = 390\,000\,000$ gal. storage, and in the San Francisco case $260 \times 5. = 1\,300\,000\,000$ gal. storage.

REINFORCED CONCRETE RESERVOIR AND COAGULATION PLANT AT ST. LOUIS, MO.

Discussion.*

BY MESSRS. A. W. BUEL, AND EDWARD WEGMANN.

Mr. Buel.

A. W. BUEL, M. AM. SOC. C. E. (by letter).—The author assumes the ratio of the coefficient of elasticity of steel and concrete at 10, which would seem to be low enough for any purpose, and sufficiently safe. Then, in the formula for the value of T, if the writer understands it correctly, the author seems to use a ratio of 9, making the tension in the steel, for 290 lb. per sq. in. in the concrete, only 2 610, instead of 2 900.

It would be interesting to know what the comparative cost would have been if, instead of proportioning the thickness of the concrete on the theory used by the author that vertical cracks would not develop if the tension be limited to 290 lb. per sq. in., the concrete had been made with a uniform and minimum thickness from top to bottom and with a separate water-proof lining inside. Unless there is a considerable saving in cost, the separate water-proof lining would appear to have the advantage of the other method, on the ground of many successful precedents.

Mr. Wegmann.

EDWARD WEGMANN, M. AM. SOC. C. E.—Although not directly a discussion of the paper under consideration which the speaker has been asked to discuss, it may be interesting to describe the recent partial failure of the reinforced concrete Ambursen dam, built in 1912 and 1913 across Stony River in West Virginia, for the West Virginia Pulp and Paper Company.

In the fall of 1911, this company engaged the speaker's services as Consulting Engineer to examine the site selected for its dam, report whether it was suitable for this purpose, and recommend the

*Continued from February, 1914, *Proceedings*.

Mr. Wegmann.

type of dam that should be constructed. The dam was to be built on top of a mountain at the end of a log railroad. Owing to the great depth to rock, the cost of a masonry dam was prohibitory. There was no suitable material available for an earth dam, and therefore the speaker recommended that a hollow dam of reinforced concrete be built.

After a number of test pits had been dug and some borings had been made, four construction companies were invited to submit plans for the dam and bids for its construction. Before doing so, each of these companies sent a representative to inspect the site of the dam and the test pits. The plans submitted have been fully described.* Each construction company bid a lump sum for building the dam with a cut-off wall down to a certain assumed probable depth. Below this depth the cut-off wall was to be paid for by the cubic yard.

The dam was to be about 1 000 ft. long and was to have a maximum height of about 50 ft. above the surface. The lowest bid was $143 000, received from Mr. F. G. Webber. The bid of the Ambursen Hydraulic Construction Company, of Boston, was $189 000. In view of the fact that the latter company was the only one of the four bidders which had built a large number of reinforced concrete dams, the speaker recommended that the Ambursen Company be engaged to make the plans for the proposed dam. This was done. The contract for building the dam was awarded to Mr. Webber. To insure that the work would be properly done, the Paper Company engaged one of the engineers of the Ambursen Company to be constantly on the ground during the construction.

Mr. Webber began work at the west end of the dam and built about half the structure. The work was then taken away from him, as the progress he made was not satisfactory, and the dam was completed by the Ambursen Company at cost plus a certain percentage for profit.†

It appears that for about 200 ft. from the west end of the dam, the cut-off wall was founded on hard clay, and was made only 5 ft. deep below the floor of the dam. This shallow cut-off wall was built to where the water was from 30 to 35 ft. deep. For the remaining length of the dam, the cut-off wall was founded on rock. This part of the dam has remained intact.

The failure was caused by water finding its way under the cut-off wall, through a permeable, narrow seam of stone, sand, etc., that occurred in the clay formation. If the cut-off wall had been carried down a foot or two deeper, it would have intercepted this seam.

The water that passed through the seam showed itself in the weepers of the floor three or four days before the failure occurred. The

* *Engineering News*, September 5th, 1912.

† The manner in which the dam was built is described in *Engineering News*, of January 22d, 1914, and in the same issue there is an account of the failure of about 75 lin. ft. of the dam, three or four months after the reservoir was filled.

watchman, left in charge of the dam, did not appreciate the danger this leakage indicated. It was only a day before the failure, that it occurred to him to inform the Superintendent of the Paper Mill at Luke, Md., about the leakage, which was steadily increasing in volume. Mr. Wegmann.

At that time a blizzard was raging and the temperature was 10° below zero. When the Superintendent arrived, the following day, the dam had been undermined and about 75 lin. ft. of the structure was destroyed.

The accounts of this failure which appeared in the daily newspapers were greatly exaggerated. The reservoir stored only about 800 000 000 gal. From the dam to the Potomac River, Stony River flows through a wilderness, the only building being a trapper's hut. The damage done, exclusive of the destruction of part of the dam, was very slight.

The failure was evidently due to the shallowness of the cut-off wall. In asking for lump bids for building the dam, the engineer of the Paper Company and the speaker had to assume certain depths to which the cut-off wall would probably be built. This depth was made 7 ft. below the top of the floor of the dam at the ends of the structure, 10 ft. where the depth of water was from 20 to 25 ft., and the wall was to be carried down to rock in the center of the valley. At each end of the dam sheet-piling was shown. The depth to which the cut-off wall was to be built had to be determined, of course, during the construction.

As actually built, the core-wall was founded on rock for about three-quarters of the length of the dam, and for the remaining length it was made only 5 ft. deep below the bottom of the floor of the dam. No sheet-piling was used.

The speaker's connection with the work ceased when the contract for building the dam was awarded, which was before the plans prepared by the Ambursen Hydraulic Construction Company had been received, and he had nothing to do with the construction.

STEEL STRESSES IN FLAT SLABS.

Discussion.*

BY MESSRS. EDWARD GODFREY, H. E. ECKLES, AND SANFORD E. THOMPSON.

Mr. Godfrey.

EDWARD GODFREY, M. AM. SOC. C. E. (by letter).—The flat slab has repeatedly been brought before the Engineering Profession for consideration and adoption, on the plea that it is efficient and economical. Before adopting it, however, the Profession has a right to examine its credentials. The theory of the flat slab must pass muster; and tests on it must be consistent and rightly interpreted. Some things in reinforced concrete design have been adopted, which have not met these conditions. They were adopted in ignorance and have been the cause of unnumbered wrecks. One of these is the stirrup or short shear member, another is the rodded column with no lateral reinforcement; but these will be rooted out in time. That they ever received the sanction of the Profession is a disgrace. It will not do to add to the number of such ill-considered standards by the adoption of any other untried and illogical method of design.

The theory of flat slabs, as given by most writers, would tend to place it in the innocuous class, for the great thickness of slab demanded would put it "out of the running"; but the commercial designers succeed in scaling down the bending moments to a point which independent practising engineers fear to attempt.

The flat slab theory premises a slab of indefinite extent, supported on an indefinite number of columns, the entire slab being uniformly loaded. The term, cantilever flat slab, so often used, conveys the idea that over the column heads the slab is a cantilever. The premises and the several assumptions are faulty. The slab is not of indefinite extent.

* This discussion (of the paper by H. T. Eddy, Esq., published in January, 1914, *Proceedings*, but not presented at any meeting), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Godfrey.

It must end at the outer row of columns or a short distance beyond them, and sometimes there are only two or three bays. Sometimes there is a girder or wall at the outer edge and sometimes there is not. Manifestly, when the outer row of columns is reached, there must be—in order to satisfy the theory—something to take the place of the continuous slab that will supply its equivalent. A girder or wall on the line of the columns does not perform this office, as a girder cannot hold a slab in a fixed horizontal position as though it were a cantilever. A continuation of the slab beyond the column line cannot supply the condition necessary, unless it is uniformly loaded with just the proper balancing load. This uniform load, however, would of necessity include some live load, and there is no law compelling an owner to dispose the load on his floor in any given way.

The idea that the slab is a cantilever over the column means one of two things. Either the load on the slab must be properly balanced, or the columns must be subject to a bending moment due to live load to one side of the column line. To assume that the live loads are always properly balanced over the columns is to restrict the owner in the free use of his structure and to demand something unthinkable. To make the columns carry the cantilever load of the slab is to subject them to stresses for which they are never calculated.

On page 67* the author says:

"The stress at 11 in the wall panel, *C*, was larger, and amounted to 20 500 lb., which probably was due to the cantilever action at the wall being less than that exerted by the usual column heads."

Here is a confession that the column heads, which means, of necessity, the columns, are depended on to take cantilever stresses from the floor.

It may be urged that the stiffness of the slab will make it capable of taking at least a part of the bending moment beyond the column line. It cannot possibly take all of it without either infinite stiffness or articulation in the column. Any theory is wrong that does not follow to an ultimate and adequate support or resistance the loads or strains assumed on part of a structure. A slab theory that ignores the effect of the slab on the columns, and leaves the reader to infer that these columns are centrally loaded, is wrong.

Another part of the theory that is wrong is the assumption that Poisson's ratio has any application to the steel reinforcement. The author's theory for the mushroom slab assumes that the steel reinforcement is equivalent to a continuous flat sheet of steel. This is contrary to fact and reason. A set of cross-rods does not in any sense fulfill the conditions that make it equivalent to a single sheet of steel.

* *Proceedings*, Am. Soc. C. E., January, 1914.

Mr. Godfrey

It is freely admitted that when a sheet of steel is pulled in one direction it contracts in the other direction. As to whether this contraction is equivalent to a compressive force that would give the same amount of shortening is another question. If this is applied to two sets of transverse rods, an entirely different condition exists. The only medium between the sets of rods is the concrete. In a previous discussion* the author has stated that for the mushroom type Poisson's ratio is five-tenths. For the type that he delights to honor, then, here is what this statement means. A 1-in. square rod stressed to 16 000 lb. is pulled crosswise by the concrete 8 000 lb. for each inch of its length. The concrete might have an adhesion one one-hundredth of this amount. Where does the other ninety-nine-hundredths come from?

In asking the Profession to accept this mushroom theory, the author is asking us to consider the laws of matter suspended for this particular type, or else that there are special laws that apply to this special combination of materials. The theory of flat slabs is hard for any disinterested engineer to accept; let us look at the tests.

The author finds agreement between his theory and the result of tests. According to his statements, deflections and extensions in the steel would seem to bear out his theoretical deductions. This apparent agreement is explained by two things, one is tension in the concrete, and the other is large columns that are only partly loaded by the tests and, therefore, can lend some of their unused strength toward resisting cantilever action.

There can be no doubt that tension in the concrete plays a large part in resisting bending moments, and consequently carrying the loads. This is true of other forms of reinforced concrete, as well. In a simple beam or slab a very large part of the bending moment is resisted by tension in the concrete; but the accepted theory ignores this tensile strength entirely, and wisely so. This is the reason that deflection calculations for reinforced concrete beams, based on no tension in the concrete, are worthless.

In a flat slab, the tensile strength of the concrete has vastly more influence in supporting loads or resisting bending moments than in a simple beam, because of the fact that the tension is in all directions. Deflection is diminished and steel stresses are reduced by reason of this tensile strength of the concrete, and any theory that tries to explain these results through the supposed influence of Poisson's ratio is false. It cannot be gainsaid that, if a flat slab were cracked along certain lines, the steel stress and the deflection would be found to be very much more than they are in a whole slab, just exactly as the same would be true in any reinforced concrete beam or slab.

Tests on a flat slab, that are manifestly very greatly influenced by the tensile strength of the concrete are falsely interpreted, when the

* *Proceedings*, Am. Soc. C. E., for August, 1913, p. 1368.

Mr. Godfrey.

effect of that tensile strength is totally ignored, and, instead, Poisson's ratio (a thing that applies only to "any piece of material which is subjected to stress, and is of such shape that more than one of its dimensions is considerable,"* hence not to a rod) is brought in to explain the low stress in the steel.

If the commercial investigators frankly admitted that the tensile strength of the concrete is their mainstay, users of the flat slab would adopt it with their eyes open, if they had the temerity to use it.

The author has published† a test on a mushroom slab which purported to show the great strength of this style of construction and its agreement with theory. This slab, though only 18 ft. square, was supported on four comparatively enormous and very short reinforced concrete columns. It was loaded with balancing loads, that is, the first and second increments of the load were partly within and partly without the square enclosing the columns, which was 12 ft. each way.

Of course, such columns would have large influence in carrying cantilever loads, because of their 18 in. of width and their small direct load, but this is totally ignored in the author's theory, and all the strength is attributed to the virtue of the system. A building could not be commercially designed with columns about half as thick as their height and a safe load of less than 100 lb. per sq. in. This test is so far from representing anything in practice that it has not even a theoretic interest, especially when the theory absolutely ignores the greatest factors in supporting the loads.

Furthermore, balanced loads on this test slab tell nothing whatever of what the slab would do if the loading were confined within the square enclosing the columns.

The dishing effect of a flat slab is often referred to as explaining the strength exhibited in tests and there is no doubt that for an interior loaded bay, with the surrounding bays idle, the dishing has a large influence. The writer has shown, by tests,‡ that though dishing in an interior panel greatly increases the strength of that panel, a row of loaded panels will not show this dishing, and will not have this large strength. The tests which have been made on flat slabs in buildings have been on one or more interior panels (including in some cases exterior panels supported on walls or girders) but never, so far as the writer can learn, on a complete row of panels across a building. Under such loading, the slab would tend to take a cylindrical shape instead of being dished, and the concrete and the steel will be under very much greater stress.

A flat slab on rows of columns is no better conditioned than the same slab supported on parallel lines of girders. No commercially

* As defined by Dr. Eddy in *Proceedings*, Am. Soc. C. E., for August, 1913, p. 1364.

Mr. Godfrey

designed flat slab will stand up under this criterion, that is, considering the slab supported on two lines of girders and figuring its bending moment as an ordinary slab subject to the common laws of Nature to which other than "flat slabs" are amenable. The writer has made these statements a number of times; they have never been controverted. This is the case of the flat slab in a nutshell. It stands or falls on the criterion just mentioned. In one notable case it fell with disastrous results.

The most serious aspect of this reliance on tension in concrete is in the case of rolling or jarring loads, as for a freight terminal or a viaduct. Repeated jarring of the load will in time crack the concrete. Then the steel will get its full load, which is several times that for which it is calculated, and trouble may be expected.

Mr. Eckles.

H. E. ECKLES, M. AM. SOC. C. E. (by letter).—The writer is glad to note the author's attempt to formulate conclusions in a more practical way than has characterized some of his past efforts. The assumption of a value for Poisson's ratio for steel and concrete in combination at four or five times its probable value, as shown by the published results of experiments with these materials in combination, and one-third larger than the sum of the ratios for the materials when not in combination, and used by the author in one of his published works in the derivation of formulas similar to those presented in this paper, accounts for some of the discrepancies between former theories and conclusions based on facts. The variations in flat-slab design and the growing importance of this type of construction are so great that attempts to formulate conclusions should be made with care, and with a view to general applicability rather than in support of a particular type of construction.

Much has been written regarding the action of flat plates under loads, and the writer believes that considerable of what has been put forth as a proper basis of design by advocates of reinforced concrete flat-slab construction is erroneous, and that the formulas proposed by the author in this paper give resultant stresses in the steel much less than would be developed under working conditions and proper test loading.

It should be noted that the results found by using the proposed formulas are compared with the observed stresses in the steel in the slab of Panel D when there was little load on the panels adjacent to it. In the adjacent Panel A the equivalent uniform load was about 260 lb. per sq. ft. of floor; in Panel C it was about 30 lb. per sq. ft.; and in the two other adjacent panels there was no load whatever. Our knowledge of this construction warrants us in believing that the effect of the surrounding floor in supporting the load of a single panel is quite large.

Mr. Eckles.

The writer recently conducted a test of a floor of the "mushroom" type of construction, having panels of the same dimensions and with a slab 7 in. thick, reinforced, however, with a larger percentage than usual of slab steel. The design load was 200 lb. and the superimposed test load was 400 lb. per sq. ft. of floor. The results of this test showed a remarkably large effect on the deflection at the middle of the panel, when parts of the adjacent panels were loaded with a full test load along two sides.

The adjoining panels were of the same dimensions and reinforcement as the one loaded. The panel tested was at the corner of the building, supported on two sides by wall beams, and corresponding to that of the corner panel shown in Fig. 1, having Columns 9, 10, 11, and 48 at the four corners.

In the first stage of the test, the panel only was loaded. Care was taken to leave clear passages so as to prevent any arch action.

The second stage consisted in loading areas 4 ft. 6 in. wide adjacent to two sides of the loaded panel, for the full length of the side of the panel, with the same uniform load as that on the panel. This placed a full test load practically over the full width of the belt of bars extending from column to column and parallel to the sides of the panel. After the placing of this additional load, the measured deflection at the center of the panel was exactly twice that found when only the full area of the panel was loaded. The measurements were made very carefully by two direct methods, to avoid any error, and a period of 40 hours was allowed to elapse between the time of the loading of the panel and the loading of the adjacent strips of floor. It seems probable that the difference in the deflections would have been somewhat larger had the width of the adjacent loaded strips been greater.

This is in harmony with the results of tests given in papers presented* some months ago, in which it was shown that loads are distributed laterally for a distance beyond the boundaries of the loaded area, in some cases amounting to more than one-half the span of the slab. Similar conclusions have been reached as a result of other tests. The method of arranging the reinforcement in this type of construction, shown in Fig. 1, with the belts of bars overlapping each other near the columns, would seem to indicate clearly that, for a single loaded panel, where the side belts are only partly loaded, the effective span of the diagonal belts would be decreased or largely modified. This effect would be enhanced still further by the fact that the side belts are of shorter spans and consequently subject to less deflection. This is precisely the effect of the "drop," used in the Larkin Building, and would seem to account for the approximate agreement of the results

*At a meeting of the American Society for Testing Materials.

of the calculations by the author's use of his formula, with those of the Larkin test, where the load extended over several panels. Mr. Eckles.

It has been pretty clearly established, by the numerous tests made, that the points of contraflexure are fairly close to that which the common theories of flexure would indicate, considering an elementary width of slab extending from column to column to act as a beam.

In the "mushroom" system this point is much nearer the column than in cases where the "drop" is used, and calculations made on this basis give results considerably in excess of those by the author's proposed formulas, based on partial test loads. The author has fallen into error through his disregard of the well-established laws of flexure, with the result that the conclusions in his paper are erroneous.

The advantages of the flat-slab type of construction are obvious. With the same quantity of material, the structure can be made approximately of the same strength as when the usual slab-and-beam type of construction is used, without excessive deflection, and with the added advantage, in many cases, of greater clearance, or a reduction of the cost by a less height of structure being required. With these facts in view, it is questionable practice to advocate a flat-slab type of construction designed under specifications inconsistent with what is recognized as good practice in the more common slab-and-beam type.

One of the disadvantages of the "mushroom" system without the "drop" is the lessened strength in shear of the slab around the column head. At the beginning of the paper the author has advocated the use of small percentages of reinforcement, though his reasons for this are not apparent. The quantity of reinforcement often used in the "mushroom" system is one-fourth of 1%, and, considering the possible effect of the overlapping belts, with this percentage the neutral axis of the slab would be approximately three-tenths of the effective depth from the compression face at points near the column. In a slab of 8 in. effective depth, the neutral axis would be about 2½ in. from the face of the slab.

The compression side of the slab is the only part of its cross-section which is effective in shear; the shear developed on this part of the slab around the top of the column is a measure of diagonal tension, and is of very high unit value. Where a "drop" is used, this unit shear is greatly reduced. With the same total quantity of reinforcement and a "drop" of half the thickness of the slab, the unit shear is reduced approximately one-fourth.

SANFORD E. THOMPSON, M. AM. SOC. C. E. (by letter).—Dr. Eddy fails to bring out the following important conclusions from the tests on the Northwestern Glass Company's Building: Mr. Thompson.

1. The reinforcement of the slab at the column head is entirely inadequate for the design load, so that the tensile stresses in

Mr. Thompson.

the steel and the compressive stresses in the concrete are excessive.

2. The gauge lines at the column head were not placed properly, so that the readings of the stresses do not represent the maximum stresses in the steel at the column head.
3. Tests made on single panels, or with the loading similar to those on the Northwestern Glass Company's Building, Loads 5 to 7, do not produce the largest stresses in the most important part of the structure, that is, at the column head.
4. The wall panels should be designed differently from the inside panels.

Stresses at the Column Head.—By the nature of the construction, the flat slab derives its strength from the rigidity of the column head. For this reason, it is absolutely necessary to design the slab so that the tensile and compressive stresses at the column head are within working limits. In analyzing the results from the tests, it is most important, therefore, to pay close attention to the stresses at the column head.

For the column head, the most unfavorable position of the loading is when all the panels around it are fully loaded. In the Northwestern Glass Company's Building, the only loading that caused the most unfavorable condition at the column head was when Load 3 was applied, and then the total load per panel was from 93 000 to 97 000 lb., though the panels were designed for a total live load of 102 400 lb. Even for this smaller load, however, the stresses in the steel due to the live load alone reached 22 000 lb. per sq. in. If to this is added the stress due to the dead load, the total stress for the design load is more than 50% greater than that usually allowed in reinforced concrete construction. The stress referred to is at Point 111 (Table 12). Stresses just as high undoubtedly would have been found elsewhere, if the other gauge lines had been properly placed over the edge of the head, as explained later. That this stress was not abnormal is indicated by the uniformity with which it increased under the load and then decreased when the load was removed.

Dr. Eddy attributes the high stress at Point 111 to the fact that:

"It was necessary to pry the ends of the rods upward forcibly and hold them in this position by blocks under their extremities, thus putting them under considerable initial bending stress."

As the gauge line, 111, was on a straight bar belonging to the diagonal band, it is difficult to see how lifting the steel in the bands, which were not attached to anything, puts any initial bending stresses on it. Even if initial stresses existed, they would not have affected the readings of the stresses, as extensometer measurements do not indicate the actual stresses in bars, but only the differ-

ence between the stresses at the initial reading and at the respective reading under load. Any initial stress, like stresses due to the dead load, is not included in this difference. Mr. Thompson.

Mr. Eddy states, further:

"At 111, Column 36, on the edge of the loaded area, the abnormal value of 22 400 lb. was reached under Load 3. Load 5 shows no such large increase over Load 3 of observed stress in the slab rods of the column heads in Panel D as was to be expected by practically doubling the loading. This fact is apparently inexplicable."

This statement is absolutely misleading. Point 111 is in Panel C, and this panel received its largest loading with Load 3. With Load 5, Panel C had a load of only 39 lb. per sq. ft., as may be seen by referring to the detail of loading in Fig. 6. It is entirely obvious, therefore, that the stress at this point ought to be less with Load 5 than with Load 3.

Faulty Location of Gauge Lines.—The location of the gauge lines over the column head is unfortunate. As is evident from Fig. 3, all gauge lines, except 103, 107, and 111, are inside the column head. The readings, therefore, on these gauge lines cannot represent in any way the actual maximum stresses in the reinforcement of the column head.

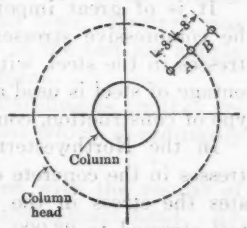

FIG. 20.

The writer has in his possession tests made by one of his associates on a similar construction, where readings were taken on gauge lines placed as shown by Fig. 20. The average results from this test gave at *A* a stress of 11 000 lb. per sq. in., and, at the same time, the stress at *B* was 24 000 lb. per sq. in. Similar results were obtained in the Worcester test, made under the direction of Mr. Brown. It is evident, therefore, that for gauge lines located like those used in the Northwestern Glass Company's Building, the results are much smaller than the maximum stresses.

This rapid decrease in stresses explains why, in Table 12, all those except 107, 108, and 111, were very low. The low stress in 103, which was placed outside the column head, is evidently caused by the fact that the gauge line was too far from the column head, and the bar was one of the outside ones of the diagonal band.

That Dr. Eddy realizes that the stresses in the rods inside the cap are much smaller than those in the same rods just after they leave the cap, is evident from the following:

"Although that part of the length of the rod which is inside the cap has its elongation prevented by the mass of the cap, the part outside must have its elongation correspondingly increased to compensate for this loss, and, on the whole, be equal to that of the rods beside it."

Mr. Thompson.

In analyzing the results from the test, however, he accepts the stresses inside the cap as the maximum stresses.

Stresses in the Concrete at the Column Head.—Dr. Eddy does not mention the stresses in the concrete at the column head. In the first part of his paper, he analyzes the relation between the stresses in the steel and in the concrete, and the influence of the percentage of steel on the stresses in the concrete. This analysis would lead one to believe that the stresses in the concrete, in the tests described later, are within working limits. This, however, is not the case. The case of "under reinforcement," mentioned by Dr. Eddy, exists within the panel. At the column head, on the other hand, the percentage of steel in the bands alone is four times that of the steel in each band. Wherever the bars overlap, the percentage is still larger. In designs similar to those discussed in the paper, the percentage of steel at the column head is between 1.5 and 2. For these percentages of steel, the stress in the concrete, corresponding to the working stress in the steel, must exceed the allowable working stress. This is evident from Table 1.

It is of great importance for the safety of the structure to keep the compressive stresses at the column head, as well as the tensile stresses in the steel, within working limits. Therefore, if a large percentage of steel is used at the column head, as is always the case in this type of construction, compression steel is indispensable.

In the Northwestern Glass Company's Building, an idea of the stresses in the concrete due to live load alone may be had if one calculates the stress in the concrete corresponding to about 1.3% of the steel stressed to 22 000 lb. With the dead load included, the stresses in the steel and the concrete would be at least 25% greater.

Loads 5 and 7 do not Produce the Worst Condition at the Column Head.—It is unfortunate from a scientific standpoint that the loading of all the panels was discontinued as soon as Point 111 received high stress. By further loading of all the panels, their true strength would have been obtained, but with the loadings as used, the results are simply misleading.

Loads 4*a* and 5, for instance, show Panels B and D loaded and Panels A and C unloaded. With this load, the stresses at the column, instead of being taken by the steel in one-fourth of the circumference of the column head, that is, by the steel tributary to that panel, were taken by the steel in one-half of the circumference. The correctness of this statement may be seen by reference to Table 12 where it is shown that although Panels A and C were not loaded, Points 103, 107, and 111, showed considerable stress. From this it is evident that the loading of Panels D and B was carried at the column head, not only by the steel belonging to Panels D and B, but also by the steel in Panels A and C. The stresses at the column head, therefore, with

this kind of loading, are much smaller than would have been the case had all spans carried loads of equal intensity. Mr. Thompson.

Other Tests on Mushroom Floors.—The student of this type of construction is struck by the paucity of reliable test data on the particular type of construction discussed by Dr. Eddy. Many tests are constantly referred to in printed literature, but on closer examination one is surprised to find that they bring out the stresses everywhere except in the most vulnerable part of the construction.

The test to destruction carried on by C. A. P. Turner, M. Am. Soc. C. E., or on his behalf, described in the engineering papers and more fully in Dr. Eddy's book, might have elucidated many mooted questions. The idea of a test panel with projections, if loaded properly, was a very good one, because the load on the projections could have been arranged so that it would have an effect almost similar to loads on the adjoining panels. The idea, however, was not carried out, and the slab was broken by loads placed in the center panel with comparatively little load on the projections. The question of the stresses in the most important part, that is, at the column head, therefore, was neglected, with the consequence that the results of the test are simply misleading to any one not well versed in the subject.

The test of the St. Paul Bread Company's Building is another instance in which everything was tested except that which is ordinarily the weakest part of the construction.

Formulas.—Dr. Eddy's formulas do not agree with the results of the tests in the most important place, *viz.*, at the column head. Although he calls them "theoretical formulas", the theoretical foundation is nullified by the many assumptions which do not agree with the actual conditions, so that the final results can lay no claim to being theoretically correct.

One of the assumptions for which no clear reason is given is that for the value of Poisson's ratio, K. As explained in Dr. Eddy's book, that ratio, for concrete alone, varies from 0.1 to 0.2. For steel alone this ratio is about 0.3. For a flat-slab construction, however, Dr. Eddy considers that neither of these two values is large enough, and he accepts a value of K equal to 0.5. To support this value, he has given a beautiful formula, but does not explain how two materials acting together can change their nature entirely, and how the top portion of a concrete slab, by merely being provided with steel at the bottom, can take on a lateral expansion equal to one-half the compressive deformation under stress. The writer does not see how this statement can be accepted by any one acquainted with the nature of the material, and yet on this assumption hangs the most vital element in the results.

The stresses for the steel in the diagonal and rectangular bands are calculated from formulas derived without regard to the size of the

Mr. Thompson.

column head, and, according to Dr. Eddy, would apply to a construction with a column head equal to a sharp point and one of any size whatever. This assumption, on the face of it, is erroneous. The stresses in concrete at the column head are simply neglected.

In determining the stresses in steel over the column head, Dr. Eddy states: "The stresses in the middle rods of each belt, consequently, are increased abnormally for this reason just as it leaves the cap."

This statement, however, does not prevent him from continuing:

"Instead of attempting to determine this increase by some intricate investigation, it will be simply assumed that the stress at this point in the middle rod does not exceed that in the outside rod of the belt at a point opposite the center of the cap."

The available tests prove the correctness of the first statement. They show, however, that the stresses in the outer bars are much smaller than those in the middle bars. Dr. Eddy's assumption, therefore, is without foundation and, as a consequence, the results from the formulas do not agree with the tests. In the Northwestern Glass Company's Building, by using the actual live load on the panel, there is obtained by his formula a stress, $f_s = 15\,400$ lb. per sq. in., while the actual stress due to live load is at least 22 000 lb. per. sq. in.

In discussing the tests, Dr. Eddy uses, in his formulas for the total load in the panel, a much larger load than was actually on the panel. As a justification for this, he states that portions of the panels near the column heads were not loaded. He overlooks the fact, however, that there were two center aisles about 18 in. wide running across the center of the panel and thus taking away the load from the place where it would be most effective in producing bending moment. The use of the larger load is still more unjustifiable in calculating the stresses over the column head, because the stresses there are more affected by the amount of load in the panel than by their position. It appears that the same load uniformly distributed would not have caused larger stresses than was caused by the load placed as shown in Fig. 5.

In discussing the Larkin Building, Dr. Eddy makes the following statement:

"It would require a load of more than 1 200 lb. per sq. ft. on such a mushroom slab to produce a maximum unit stress on the slab rods as great as was caused in the Larkin slab by the test load of 738 lb. per sq. ft."

This, of course, is calculated according to his formula, which, as has been shown, does not agree within 45% with the actual results. This claim is only another expression of Dr. Eddy's faith in the miraculous properties of this particular type of reinforcement; but, to engineers familiar with the design of reinforced concrete, it seems at least open to discussion.

Mr. Thompson.

As a conclusion, it appears, from a careful study of the tests, that a design similar to that of the Northwestern Glass Company's Building does not have the proper factor of safety required in reinforced concrete construction; that the stresses in the steel, as well as in the concrete, as is evident from Table 12, exceed those used in conservative designs; and that the formulas given by Dr. Eddy do not appear to agree with the results with the accuracy claimed by him; in fact, as stated before, the difference between the results from the formulas and the actual stresses reaches the large amount of at least 45 per cent.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

GROUTED CUT-OFF FOR THE ESTACADA DAM.

Discussion.*

BY MESSRS. S. HOWARD RIPPEY, S. C. HULSE, FRANK R. FISHER, H. L. COBURN, AND WILLIAM H. CUSHMAN.

Mr. Rippey.

S. HOWARD RIPPEY, M. AM. SOC. C. E. (by letter).—The deep interest in the subject of grouting dam foundations, as shown by numerous private inquiries from engineers in America and abroad concerning the Clackamas River experiments, renders it certain that this paper will be generally appreciated by the Profession, and it is to be hoped will develop a broad discussion of the general subject of dam foundation treatment. Although this subject is always of interest to those engaged in hydraulic work, its seriousness is from time to time given added significance by such unfortunate occurrences as the failures of the Austin and Stony River Dams, as well as of other less conspicuous structures, showing that perfectly well designed and constructed concrete dams of any type may be wrecked as a result of inadequate preparation of their foundations.

The detailed information given by Mr. Rands concerning the practical execution of the grouting programme at Estacada should be of value to others facing similar problems, but the writer fears that some of the conclusions reached by the author and the personal opinions expressed, may tend to indicate to others undue difficulties and limitations in the general applicability of the grouting method to dam problems, and to that extent discourage the use of a method which in many instances may represent the only economically practicable solution of a development project.

In order, therefore, that the results obtained at Estacada, and the conclusions drawn therefrom by Mr. Rands, may be properly appraised

*This discussion (of the paper by Harold A. Rands, Assoc. M. Am. Soc. C. E., published in January, 1914, *Proceedings*, and presented at the meeting of February 18th, 1914), is printed in *Proceedings*, in order that the views expressed may be brought before all members for further discussion.

Mr. Rippey.

by others interested in the treatment of deficient foundations, it is proper to outline, as briefly as possible, sufficient of the history of that project to indicate the unfavorable character of the governing conditions under which the work was executed.

As indicated by Mr. Rands, the use of grout at Estacada was prescribed by the writer, following thorough study of the foundation requirements at the site of a proposed large reservoir and power dam on Clackamas River, some 5 or 6 miles above Estacada (known as the Upper "Clackamas" or "Second Clackamas" project). At this site a mass concrete dam about 150 ft. high was found to be desirable as part of the most efficient plan of power development and flow equalization, but the character of the foundations (similar to those found later at Estacada), was such that the writer felt that the construction of such a dam on them would not be in accordance with any known precedent, good judgment, or the dictates of good practice, unless the objections could be overcome. It thus became necessary to decide whether to modify the development scheme so as to avoid the necessity for a high dam (as, for instance, by a low dam and a long flume to create the desired head), or undertake to improve the character of the foundations so as to justify the execution of the more efficient and satisfactory plan of development.

At this juncture the writer decided that the use of cement grout, injected under pressure, offered a possible solution of the problem of foundation treatment, and probably represented the only practicable method of treating this remarkably heterogeneous formation, so as to justify the construction of a high masonry dam on it. Test-pit and core-drill investigations in progress indicated the absolute need for novel measures in order to render the foundations fit for the proposed construction, and the formations encountered were such as to make the writer believe that the grouting method could be applied successfully.

In order to acquire a more comprehensive idea of the possible range of geological conditions to be encountered than was feasible through the local borings in progress and by superficial examination of the canyon in this locality, the writer, fortunately, was able at this time to secure a very thorough geological report from Professor J. S. Diller, of the U. S. Geological Survey, who made a personal examination and study of the canyon for the purpose. In view of the questions raised by Mr. Rands, the following abstract of Professor Diller's report is considered pertinent to the discussion:

"The rocks of the canyon walls are of four forms, volcanic breccias, lava sheets, volcanic dikes and terrace gravels. * * * The volcanic breccia (bed-rock) is made up of unassorted angular fragments of lava, andesite and basalt of various colors, ranging in size from dust particles and grains of sand to large rock fragments many feet in diameter.

Mr. Rippey.

* * * Sheets of solid non-fragmental lava forming part of the bed-rock and outcropping on the slopes of the canyon occur within and between the great sheets of volcanic breccia. Some of the lava sheets are basalt * * * generally very porous. * * * Nearly vertical dikes of basalt cut up through the sheets of volcanic breccia and lava, and their outcrops on the surface have the direction of N. 65° W. approximately parallel to the general course of the canyon. * * * There is a set of parallel joints, the open cracks of which cut up through the volcanic breccias and sheets of lava about vertically in a direction approximately parallel to the course of the canyon. * * * Such joints may be of considerable extent and form important openings for the circulation of water. Well developed joint cracks of this system were not seen in the exposed bed-rock of the dam site, but they may be expected, and should be carefully looked for where the bed-rock is covered with soil or gravel. It is especially significant that the dikes are approximately parallel to these joint cracks and suggest that these joint cracks may extend to great depths. * * * From the nature of the volcanic breccia, which forms by far the greater part of the canyon walls, it is evident that the drill cores will differ from one another very much when compared. Where the drill goes through a sheet of lava or a large solid fragment it will yield a good core, but where it penetrates the finer material (the volcanic ashes, in which the fragments of all sizes are imbedded), the core fails, the material is pulverized by the drill and washed away, and yet the extent of this material that is washed away is of the greatest importance, for it is the weakest element in the structure and the one which when saturated with water under pressure is most likely to become Engineers' 'soapstone'. Soapstone, properly so-called, does not occur in that region at all, but decomposed lava, volcanic ashes, and clay, all of which when saturated with water may become slippery and would be called 'soapstone' by Engineers, occur locally in the volcanic breccia. Large caverns and cavities, or pockets of loose earth and stones, are not to be expected in the volcanic breccia, but, owing to the manner of accumulation, there may be small openings, and the porosity of the rock is high. It is pervious to water, and for this reason similar material is used for making water coolers. The crushing strength of the volcanic breccia is, of course, small as compared with granite, limestone, and most other rocks, and this, taken in connection with its porosity and the possible existence of undiscovered joint cracks, seems to make a large reinforcement with concrete necessary, in order to furnish strength and prevent seepage as well as erosion.

"The conditions that confront the engineer along the Clackamas River in the volcanic breccia plain region are very much the same as will be found all along the western foot of the Cascade Range from the Columbia River in Oregon to the Feather River in California—one of the most important water-power belts in the United States—and the successful solution of the problem it presents at one point will greatly facilitate the work elsewhere."

At this time only one of the core-drill holes had been subjected to water pressure as part of the original programme of studying the porosity of the foundations. In a report to his clients, covering in-

Mr. Rippey.

structions to the Field Engineer, Shirley C. Hulse, Assoc. M. Am. Soc. C. E., the writer said at this time:

"The result of this test shows that 25 gal. per min., at a pressure of 175 lb., have been pumped into this hole for several consecutive hours, and, while coloring matter was used, no points of escape were noted and the behavior of the water surface in the surrounding holes has been so small and erratic as to be negligible. It has been evident since the first holes were drilled that we are dealing with a very porous and permeable foundation condition which will require special treatment to render it suitable for the construction proposed, and the purpose of the pressure tests outlined was to indicate the extent of permeability and the general lines of leakage, so that we might best plan to make the foundation of the dam impermeable. * * *

"In the Middle West, where a number of masonry structures are built on sand or earth foundations, it is customary to cover the river bottom for some distance up stream with a layer of clay and depend on the silt in the river closing up all the fissures and paths of seepage, but it would be very unwise to depend on this method in such a construction as we have under consideration. * * * It is necessary to solidify and render impermeable the formation immediately beneath our proposed dam before we are justified in building a dam at this site.

"It is evident that impermeable foundations are desirable: (a) to minimize the possibility of upward pressure under the base of the dam superstructure (this being a solid concrete dam); (b) to prevent percolation under the dam which might lead to sufficient erosion to involve undermining the structure; (c) to overcome any structural weakness due to the original geological formation, and properly provide a support for the superimposed load; and (d) to avoid waste of water (the chief power asset of the Company) from the reservoir, through, under, or around the dam, instead of through the turbines where it creates K. W. H. available for sale.

"It is * * * evident that we cannot afford to build the plant and find out afterward whether we can make the foundations impermeable, but that we should adopt a programme whereby we may hope absolutely to demonstrate our ability to render the foundations impermeable before the superstructures are built. * * * The general idea involves drilling a double line of holes under the heel of the dam and forcing into each hole grout of such consistency as to percolate through the permeable substructure and solidify it absolutely throughout the entire length of the superstructure, thus making the foundations absolutely solid and also providing the equivalent of an absolute cut-off wall. * * * Cement grout should be pumped into these holes and after time has been allowed for hardening, a third line of holes should be drilled midway between the first two lines and tested under water pressure. If water pressure is applied at or slightly above the hydrostatic pressure to which this rock would be subjected by the water in the reservoir after the completion of the dam, and it is found impossible to force any amount of water through the holes, we may feel reasonably certain that the cement grout has proven effective in making the entire foundation impermeable. * * * The test * * * may show a very large quantity of leakage, and this will simply mean that more holes would

have to be drilled and pumped full of grout. * * * The programme to be followed will be necessarily indicated to a considerable extent by the experience obtained as the work progresses. * * * In order to avoid the uncertainties consequent upon an arbitrary determination of the spacing * * * of these grout holes, as well as of their depth, it appears expedient to select a convenient site where the cores indicate as difficult a formation to make tight as any on the job and to use this site as an experimental laboratory. * * * It seems probable, however, that this experiment may be made as part of the preparation of dam foundations, and the total cost of the work thus kept at the minimum. * * * We still regard it as essential that our ability to make the foundations tight be absolutely demonstrated before the work is started on the dam, and the experimental programme outlined provides for such demonstration." Mr. Rippey.

This report included detailed descriptions and sketches unnecessary to reproduce here.

At about this time the company acquired from other interests the "River Mill" property, below Estacada, and for business reasons decided to push a development there to early completion. The programme adopted by the owners of the properties provided that the detailed surveys, foundation tests, and preparation of detailed plans be made by the local organization and submitted to the writer, as Consulting Engineer, for his criticism and approval. The instructions issued specified: "This particularly applies to the foundation, as no chance or risk must be taken of locating a dam upon unsuitable foundations".

The general character of development adopted was similar to that already planned for the higher-head, upper project, except that the hollow reinforced concrete type of dam, which the writer had selected for two earlier successful developments in New England, was adopted on his recommendation, and the grouted preparation of foundations on the general plan in progress at the upper site was prescribed.

The programme adopted in the interest of saving time, with the writer's hearty approval, was soon violated in many respects by the local organization (the personnel of which has since changed). The construction programme being followed was found to be such as the writer could not approve, and he, therefore, advised his clients that the modifications locally made in the foundation treatment were "beyond the limits of the precautions which should be taken in such an undertaking, and while no one can claim with any assurance that failure will result, I cannot conscientiously approve the programme adopted, nor assume any responsibility in connection with it."

The writer also stated, in another communication:

"The successful treatment of the foundations is dependent to a large extent upon the detailed methods adopted, but it is also dependent upon the spirit with which this work is carried out. Your organization has already expressed the opinion that detailed studies and

Mr. Rippey.

grouting are unnecessary, and, further, that detailed programmes prepared in advance of actual exposure of foundations are useless.

"We therefore feel that, aside from the engineering questions involved, your organization has not a proper appreciation of the subject; and further, any programme that may be insisted upon which is not in accord with their ideas would not be carried out in the proper spirit."

The foundation work had been held up for several months because of the writer's inability to approve what was proposed and the unwillingness of the local organization to follow the programme ordered, when the President of the Company suggested that John F. Stevens, M. Am. Soc. C. E., late Chief Engineer of the Panama Canal, be asked to pass upon the questions at issue. As a result of the opinions expressed by Mr. Stevens* (who was practically an arbitrator selected by the local parties), the owners of the property were confirmed in their support of the judgment of the writer, and insisted on the work being properly executed. So much time had been wasted, however, and the urgent need for power was so great, that it became necessary to carry along the grouting work in connection with actual construction of the superstructures in the best possible manner under the circumstances, and the conditions were not ideal for the development of the full possibilities of the use of grout.

The reversal of the local authorities and their reluctant acceptance of the ordered programme produced an attitude which resulted in unnecessary difficulties, obstructions, and personal controversies on the ground, finally leading to another change of Resident Engineers, for

*By the time the situation was formulated for presentation to Mr. Stevens, the local organization had developed a programme for the drilling, testing, and grouting of foundations, coincidently with or subsequent to the construction of the dam and other superstructures, instead of prior thereto, and his formal report, therefore, related largely to a comparison of the methods of execution, rather than to the accepted fundamental necessity for grouting the foundations. The following extracts from his report, however, indicate clearly his attitude on the larger question and his appreciation of the importance of foundation treatment:

"The limited number of test pits and borings which have been made shows clearly that, as far as concerns the area they covered, no well-defined, extremely hard masses of rock exist—that the rock is soft and shades away into clay, the latter appearing under superficial examination much like a half-burned brick. The whole formation, to the non-geologically scientific man, seems to be a mass of soft conglomerate, * * *

"The writer regards it as unfortunate that more test holes were not put down. * * * Enough testing, however, has been done to establish the fact that seams, or fissures, or cavities, do exist where certain of the holes were put down, and therefore it is only fair to assume that they exist where no testing was done; in fact, the only safe assumption is that they exist all over and through the formation, but to what sizes and shapes no one can say. There is no doubt in the mind of the writer that all such seams or cavities can be filled and sealed to exclude water by the proper introduction of cement grout. * * * If liquid cement under 200 lb. pressure cannot be forced into the material, the water under 35 lb. cannot find its way, and the writer concurs in such opinion. * * * Grout to be forced in by compressed air under 200 lb. pressure, the flow to be continuous from start to finish. This the writer believes to be the most practical and best method. * * * the writer believes that the material is, over the greater part of the area, porous enough so that under the heavy pressure the grout would form a practically continuous body, or curtain, from 12 to 15 ft. in thickness. * * * No living man can guarantee the absolute success of the grouting when it is placed."

purely personal reasons. Under all the circumstances, it reflects great credit on the ability and adaptability of all the engineers engaged on the work that they were able to attain as good results as those described by Mr. Rands in the face of aggressive lack of sympathy displayed by the local organization toward the foundation programme. Mr. Rippey.

As his clients loyally supported the writer's judgment in these matters, he regrets the necessity for discussing them in this connection, and at this late day. The Profession, however, is entitled to a knowledge of the actual conditions of the execution of the work, in order that other engineers may not be misguided by the results and by the opinions expressed. Moreover, as the writer's connection with the undertaking has been thus publicly recorded by Mr. Rands, the foregoing explanations properly become part of the record.

It must be understood that although the writer in 1910 declined to be considered responsible for results, in view of the conditions developed through the continued disobedience of governing instructions, he has no reason to question the safety of the final construction, which was nominally completed along the ordered lines, although under many handicaps.

While the Estacada work was in progress, the company acquired other partly developed power properties, and the Upper Clackamas development was therefore postponed before any conclusive results had been reached in the grouting experiments at that site.

About 2 years ago, in discussing the Estacada Dam in relation to the original experiment, the writer stated:

"It will be evident that the question of uplift pressure under a dam of this type is practically negligible, and, as the static head created is only about 83 ft., the other risks incident to a permeable foundation become proportionately smaller. As an indication of the porosity of the foundation material, it was found that the average leakage through 43 holes each 50 ft. deep (individually tested) was at the rate of 82½ gal. per min. under an average pressure of only 17.7 lb. per sq. in. The problem here becomes that of reducing the permeability to reasonable limits to overcome any structural weaknesses, prevent objectionable erosion and limit waste of water, without insisting upon the degree of tightness which would be necessary if the upward pressure under the dam base were a factor. The work was very urgent and the construction programme was modified in numerous respects to meet the exigencies which developed, but the dam was completed in November, 1911, and the foundation treatment appears to have met the practical requirements, although it was not pursued to the extent required to entirely eliminate upward pressure (had a solid dam been adopted).

"The holes were not uniformly spaced throughout the foundation, being located as experimental tests and the related construction work indicated best under the circumstances, and while the dam has been successfully completed and the plant is in regular operation, it is probable that the foundation treatment could be more thoroughly and

Mr. Rippey.

economically effected in another case if taken up vigorously during the preliminary stages of a development so as to be independent of construction complications. Moreover, the practical experience obtained should greatly facilitate adapting this method to another development. It will be quite obvious, however, that each site will have its own peculiarities, and radically different treatment may be required."

Although the writer thus recognized the incompleteness of the grouting results attained as a result of the conditions described, and the degree of subordination of the grout work to the construction programme, which existed, it does not appear that the results were as negative as might be inferred from some of the personal conclusions reached by Mr. Rands. The very large quantity of cement introduced into the foundations necessarily represents an improvement in the formation to that extent, aside from any interpretation of pressure-test results, and, as Mr. Rands states, tests made after completion disclosed no leakage of water past the cut-off as the result of a hydrostatic head of from 80 to 90 ft. above the dam.

Although the final official report of Mr. Frank R. Fisher, who was Resident Engineer in charge during the period of completion of the development, indicates clearly that the grout did not produce impermeability over certain limited areas, it shows very definitely the practical sufficiency, for the purpose, of the results attained, as indicated by the following quotations therefrom:

"The excavation of the trench for the supplementary cut-off wall, in the locality where grouting had previously been done, afforded an excellent opportunity for observing its effects, as many seams were exposed, and all of them proved to be well caulked with cement. None of any magnitude were observed, the largest ones averaging about ½ in., and varying from that down to $\frac{1}{16}$ in., the smaller ones also having taken the grout freely.

"There was a total of 29 proving holes put down on this [the right channel] section, and, discarding the tests on two of them that represented excessive leakage that was only local, the average for the remaining 27 was 3.6 gal. per hole. In material of this kind this was not considered excessive, and it is reasonable to assume that for all practical purposes the cut-off is effective on the right channel section.

"*Conclusions.*—The final conclusions to be drawn * * * may be stated as follows:

"*1.*—It is not feasible to accomplish an absolutely impervious cut-off by this method, in foundation material of the character that exists in this region. The method apparently is effective in closing up seams and crevices of appreciable size, as all such exposed by the excavations made subsequent to the grouting were tightly caulked with cement.

"Where seepage occurs through a more or less porous formation, or through veins of compact broken rock mixed with sand or a certain kind of clay rock, very much seamed, but with the joint or cleavage faces in close contact, all of which have been observed to exist over very

limited areas in this locality, the grout has but slight effect in benefiting the condition. Material of this character acts as a filter, the cement remaining in the hole, and it cannot be diffused throughout the surrounding mass. Mr. Rippey.

"*2.*—While the grouting did not result in an impervious cut-off, the amount of possible seepage through the foundations was very much reduced thereby and it may be considered tight to the extent that erosion and appreciable waste of water would not occur.

"*3.*—The tests on the two holes put down inside of the dam, after the filling of the pond, indicate the presence of some upward pressure in the foundations. It is questionable, however, whether this could be prevented, even with an impervious cut-off 50 ft. in depth, for the indications are that the material in this particular locality is such that water would travel downward and pass under any depth of cut-off that it would be practicable to accomplish.

"*4.*—As it has been proven that the foundations cannot be grouted absolutely tight, it is obvious that but little good is accomplished in attempting to reduce still further what might be termed a reasonable rate of seepage by the introduction of additional holes."

The interest manifested in the Clackamas grouting experiments and the successful adoption of similar methods elsewhere clearly demonstrate the fundamental merit of this method of treating deficient foundations. Indeed, in some cases it appears to the writer to afford the only practicable means of rendering certain formations satisfactory for the construction of high solid masonry or concrete dams. The problem of eliminating upward pressure under the base of solid dams, the significance of which was emphasized in the discussion of a paper* by the late C. L. Harrison, M. Am. Soc. C. E., is peculiarly susceptible of solution by the grouting method in certain formations. In the course of the discussion on that paper, Arthur P. Davis, M. Am. Soc. C. E., said:

"Recent experience has shown the feasibility and efficacy, in some cases, of closing the crevices in the foundations wholly or partly by grouting them under pressure. This was accomplished successfully at moderate cost on the Ashokan Dam, and on several others of recent construction. The most striking instance of this kind which has come to the writer's attention is the Clackamas Dam, in Oregon, which was built on a foundation of semi-indurated volcanic ash, which was checkered in all directions by innumerable fissures, and, furthermore, was so soft that percolation was likely to cause destructive erosion. A triple line of holes was grouted along the up-stream toe of this dam, and recent information is that, since the dam has been in use, no perceptible percolation has taken place.

"The effect of such grouting is not easy to foretell, and, like all other underground conditions, must be estimated with extreme caution."

Incidentally, it was the failure of the local organization to recognize the necessity for this extreme caution, as emphasized by so ex-

* "Provisions for Uplift and Ice Pressure in Designing Masonry Dams," *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 142.

Mr. Rippey.

perienced an authority as the Chief Engineer of the U. S. Reclamation Service and insisted on by the writer, in connection with the Clackamas work, which led to the unfortunate lack of sympathetic co-operation at Estacada.

A private letter from certain foreign engineers who had inquired about the Clackamas grouting experiments, from which the writer does not feel at liberty to quote directly without permission, reported the complete success of grouting to create an impermeable mass of a defective formation through which water freely escaped from a reservoir. It appears that the greatest success was secured by using a very dilute grout mixture, starting with quite low pressure, and finishing with pumped injection, whereby a certain amount of shock was applied which tended to overcome any temporary obstruction. It was demonstrated that the grout, which set well, traveled more than 100 ft., in plan, and the results appeared satisfactory in the highest degree.

In a recent article in a technical journal,* D. W. Cole, M. Am. Soc. C. E., Project Engineer, U. S. Reclamation Service, describes the application of the grouting method to the foundations of the Lahontan Dam of the Truckee-Carson Project. The writer understands that Mr. Rands was in direct charge of the grouting work (following the completion of the Estacada work), and Mr. Cole describes the results as "excellent", evidently considering, in advance of the completion and filling of the reservoir, that they were successful in accomplishing their purpose. He refers to the fact that it was proven that the grout hardened in place and gives evidence of the effectual sealing of fissures and seams and the solidification of the foundations adjoining the grouted holes.

Another article, in the same journal,† describes the grouting work done on the foundations of the Olive Bridge Dam of the Ashokan Reservoir, part of the Catskill water supply project for New York City. Two definite planes of slight seepage, 40 and 60 ft., respectively, below the creek bed, were found. It appears that 1 439 cu. ft. of thick grout were injected (under comparatively low pressure), of which it was estimated that 1 100 cu. ft. entered the seams. No proving tests seem to have been made.

Ample evidence exists to demonstrate the broad possibilities of the grouting method in its application to the solidification of defective foundations, and it remains for the engineer in each case to adapt it to local requirements. Of course, no general engineering method or formula can eliminate the need for experienced judgment in its detailed application, and, in work of this character, sympathetic co-operation is necessary, down to the humblest participant in its execution.

---

* *Engineering Record*, March 29th, 1913.

† *Engineering Record*, April 8th, 1911.

Mr. Rippey.

The writer believes that the grouting method affords many economical possibilities in water conservation and power development. It may permit the creation of an operating head entirely by a high dam, instead of by a low dam and a long, and perhaps leaky, flume; it may permit the selection of a site for a dam where the topography is favorable but where the natural foundation is impossible or not as satisfactory as at some poorer power location on the stream; and in many ways may be developed to render reservoir and power problems more flexible.

Even where the security of the construction may not be in question, the prevention of waste by percolation may amply justify the grout treatment to secure impermeability. At the Upper Clackamas, for instance, it was estimated that a saving of only 26 sec-ft. would justify an expenditure of $80 000, aside from any of the collateral advantages (there real necessities) of preventing the flow of water under the dam.

It is difficult to imagine any alternative method of foundation treatment in which the range of possibilities is as great as in grouting.

It will be observed that an essential feature of the grouting programme proposed by the writer is the ability to demonstrate by test, before building the superstructure, that the solidification of the porous material to a satisfactory degree of impermeability has been effected. The holes drilled by rotary drills for securing core specimens, and thus studying the foundations, were utilized later for the hydrostatic pressure testing, for washing out loose and soluble material, and for the introduction of grout under pressure. In the peculiar and exceedingly variable material encountered, it was found that in some cases communication existed between holes as far apart as 70 ft., and in other cases grout could not be made to permeate the material sufficiently unless the holes were very close together. The result was that a greater number of grout holes were required than was tentatively assumed without any experimental knowledge whatever, and a greater number than were required for core studies alone. This fact suggests that, in other applications of this method to large undertakings, only sufficient core holes be drilled by rotary drills to permit proper studies of the geological formation and general foundation structure, and that the remaining holes be sunk purely for grouting and testing purposes by apparatus which will perform the work more rapidly and economically.

The nature of the operation involved in securing cores is such as to necessitate slow progress and relatively high cost per foot of drilling, and when the writer reached a point on the original work where he was not specially interested in securing additional core samples, and where the results showed the need for closer spacing of grout

Mr. Rippey.

holes than was thought from the general appearance of the rock and its permeability to clear water would be necessary, he considered the use of drills which would perform the remainder of the work more expeditiously and at less cost than was possible with rotary drills made primarily for securing cores.

The average rate of progress with the core drills was about 13 ft. per 10-hour shift, and it was evident that if the further work was confined to plain drilling it could be done much more rapidly. It appeared that the future drilling might best be done with percussion drills with guided rods arranged so as to drill holes 6 in. in diameter and about 50 ft. deep, approximately plumb, at a high rate of speed. A number of drills were found on the market which could be mounted to accomplish this work, but there was great difference of opinion among the manufacturers as to the possible rate of drilling in this material, estimates running from 25 to 150 ft. per 10-hour shift. At this juncture the development was postponed, for the business reasons stated, and the subject was not pursued further, but there is evidently opportunity for great saving along these lines.

The costs of drilling and grouting at the Estacada Dam, as given by Mr. Fisher in his final report, and by Mr. Rands, on a somewhat different basis, in his paper, and the cost of grouting given by Mr. Cole for the Lahontan Dam, all reduced to a unit basis, are given in Table 5.

TABLE 5.—COST OF DRILLING AND GROUTING AT ESTACADA AND LAHONTAN DAMS, PER LINEAR FOOT OF COMPLICATED WORK.

Labor and materials.	Estacada Dam.		Lahontan Dam.
	Fisher.	Rands.	Cole.
Labor, drilling	$0.58	$0.59	$0.93
Labor, grouting	0.18	0.18	0.29
Cement	0.12	0.12	0.31
Repairs and supplies	0.17	0.17	0.23
Plant	0.30	.....	.....
Plant depreciation	.....	0.15	0.35
Power	0.05	.....	0.03
Other items	.....	.....	0.94
	$1.40	$1.21	.....
Salvage on plant, Credit	0.17	.....	.....
Direct cost	$1.23	$1.21	.....
Total field cost	.....	.....	$3.08
General plant, etc.	0.32	0.45	0.12

Engineering and superintendence	.....	0.19	0.27
Clerical and office	.....	.....	0.10
Total cost per foot	$1.55	$2.00	$3.57

Mr. Rippey.

It is of interest to note that the cost of cement per foot of hole at Lahontan was more than 2½ times that at Estacada; examination of the data, however, indicates that cement cost about $2.77 per bbl. at Lahontan and only $2.20 at Estacada. The actual quantity of cement used per foot of drilled hole appears to have been as follows:

Estacada.—34 038 ft. of holes: 1 942 bbl. = 0.057 bbl. per ft.
Lahontan.—2 593 ft. of holes; 1 174 sacks, say, 294 bbl. = 0.113 bbl. per ft.

In his final Estacada report, Mr. Fisher says: "The holes put down with the diamond drills cost about one-third more per foot than with the shot drills."

The average rate of drilling at Estacada was 1.3 ft. per hour and at Lahontan about 0.75 ft. per hour.

The use of percussion drills for grout holes after all necessary cores are taken, as has been suggested, should materially reduce the total drilling cost on a large job, and should also reduce the time element, which is of prime importance in most river work.

The writer has information concerning other successful grouting in dam foundations in a foreign development, but, unfortunately, is not at liberty to communicate it at this time. Although the method described has inherent possibilities possessed by no other system, cases may arise wherein the impregnation of an extended rock mass with grout is not necessary, but where a definite and absolute sub-surface cut-off is required. There are many difficulties and limitations incident to the construction of a cut-off wall in an excavated trench for this purpose, especially for work under a high head where the desired depth is great, and, in connection with the consideration of the grouting scheme, certain alternatives for such limited applications have been developed. No opportunity has occurred for testing these, but some suggestions concerning them appear to be pertinent to this discussion, and may lead to the further development of foundation treatment methods.

Fig. 16 illustrates the general features of a suggested cut-off; this plan contemplates drilling a single line of 6-in. holes on 9-in. centers, broaching the intervening webs so as to form a continuous slot, introducing interlocking steel piling to ensure a water-tight barrier to the passage of water, and firmly securing this steel curtain in place and backing it by concrete, in the manner shown. The introduction of this curtain would afford the assurance of a positive stop to the percolation of water, but would not provide for the solidification of the mass of the foundation so as to increase its bearing value. For this reason this method might be specially applicable to a stratified foundation where approximately horizontal seams or bedding planes containing clay or soft material constitute a source of danger only when subjected to erosion.

Mr. Rippey.

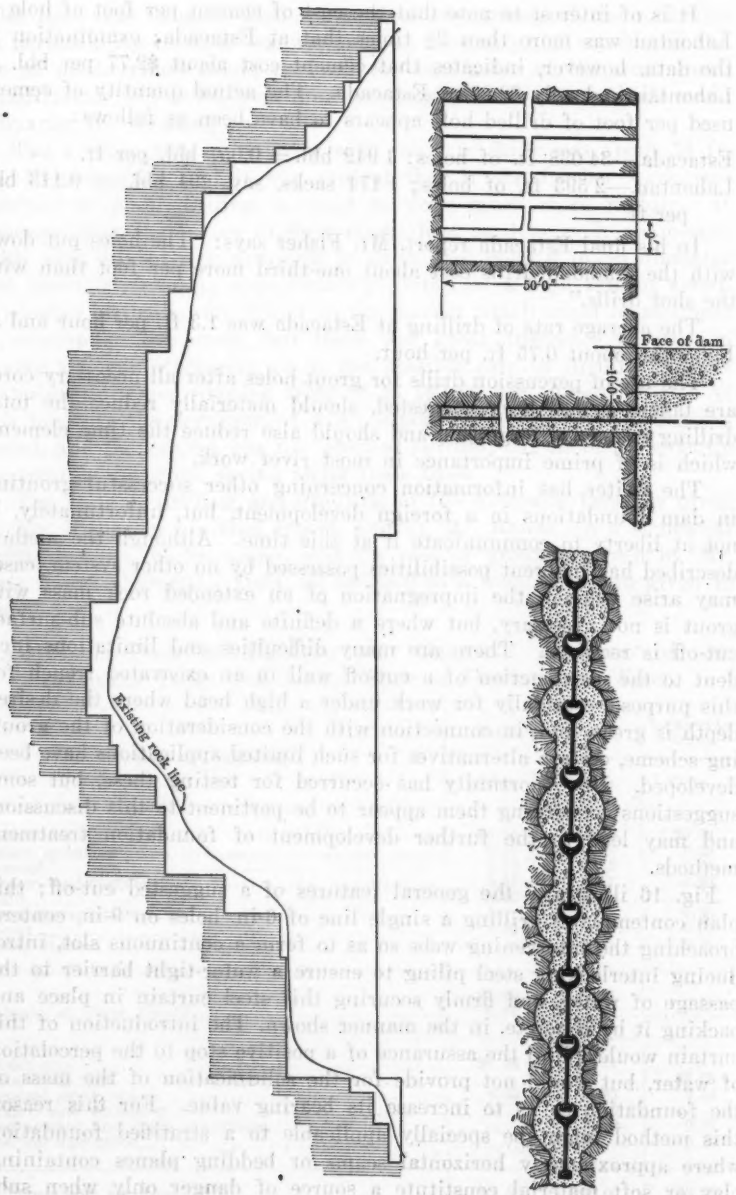

Fig. 16.

Mr. Rippey.

In considering the proposed method of constructing an effective cut-off barrier of this type, the details of execution remain to be studied. There appears to be no doubt that any one of several makes of percussion drills is capable of drilling 6-in. holes 50 ft. deep at relatively high rates of speed, but in ordinary work the question as to whether such holes are straight and truly plumb has been given little consideration. In the proposed scheme, the necessity for inter-connecting the drilled holes by broaching or blasting out the intervening webs to form a continuous slot, necessitates a certain degree of parallelism of the adjacent holes, and, as such drilling is without precedent for holes of this depth, the drill manufacturers have naturally been unable to make any guaranties as to performance in this respect, but there appears to be no doubt as to the possibility of working out this feature of the problem. Incidentally, the manufacturers have nothing to offer in the way of a machine for directly channeling such a slot as required, and the slot seems to be physically, as well as in the conception of method, the natural development of a series of holes drilled reasonably close together.

As alternatives to the plan proposed, wherein the steel curtain provides the absolute cut-off within the limits of its depth, two modified schemes have been considered:

(a) Drilling a row of 6-in. holes, A, B, C, etc., on 9-in. centers, as shown by Fig. 17, Sketch 1, filling these holes solid with cement mortar or grout, and, after setting, drilling intermediate holes, 1, 2, 3, etc., which in turn would be grouted, thus forming a continuous concrete wall of 6-in. maximum thickness, if the holes are all plumb and parallel. There would be no way of determining, however, to what extent the concrete fills the spaces, and the degree of its impermeability when set, so that there would be no proof of having accomplished the desired results.

(b) Drilling a single line of 6-in. holes, A, B, C, etc., as before and forcing grout into them, which would be expected to permeate fully the intervening rock, as indicated on Fig. 17, Sketch 2.

The assurance of impermeability with this procedure would be even less than in plan (a) and both ideas were discarded as insufficient.

Inasmuch as the creation of a continuous slot 50 ft. deep is a novel proposition, the execution of the programme would require the most careful supervision, in order that detail methods might be devised which would insure the complete realization of expectations at minimum cost. In the first place, the drill should be mounted on a frame constructed so as to be easily and quickly moved from hole to hole and maintained plumb under the powerful high-speed stroke contemplated, to the end that the holes should be as true and plumb as is practicable. When the holes in a given section are completed, the

Mr. Rippey.

broaching of the intervening webs of rock may be effected by replacing the 6-in. drilling bit with a broaching bit and disconnecting the rotating devices used for driving round holes, so that the bit may be partly rotated by hand, as required by the varying conditions

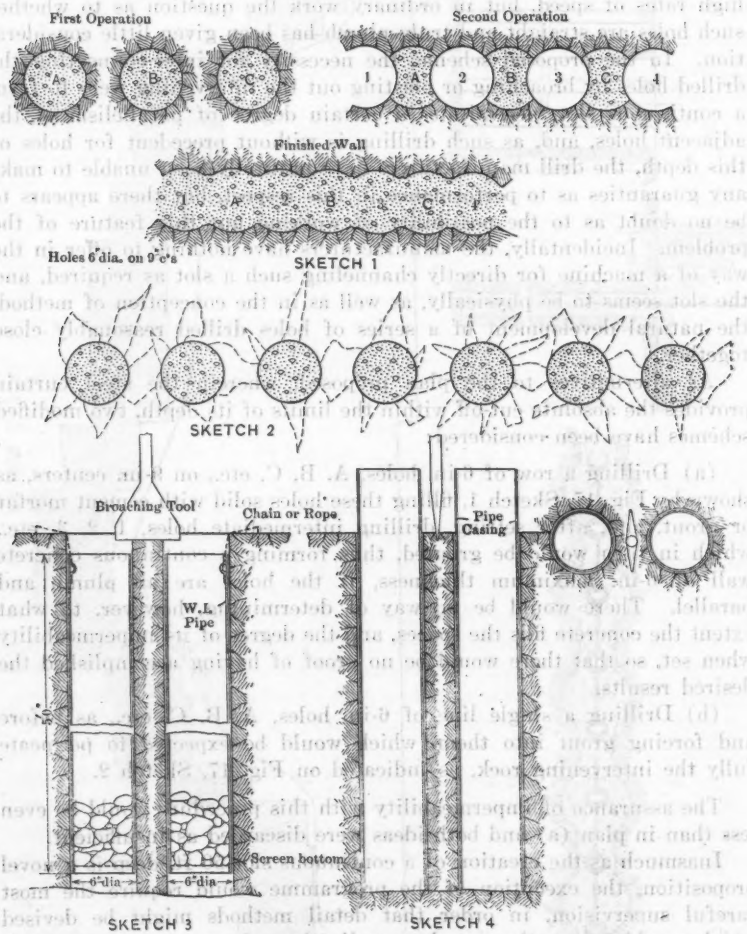

FIG. 17.

encountered. It seems possible that in some instances the original holes might deviate from the theoretical lines sufficiently to warrant drilling additional intermediate holes in places to facilitate the broaching, and it also appears possible that a limited amount of blasting might be justified in order to break out irregular webs into the con-

tinuous slot; these, however, are details to be worked out in the field during the progress of the work. Mr. Rippey.

In drilling the original holes there should be no difficulty in washing the cuttings to the surface in the usual manner, so that each hole on completion should be practically clean. There is opportunity for some ingenuity in experimenting with the broaching process, both as to the cutting and the removal of the cuttings, and it is obviously important to be assured that these cuttings are removed so as to interpose no obstacle to the introduction of piling or the complete filling of the slot by solid concrete. This cleaning out of the broach-

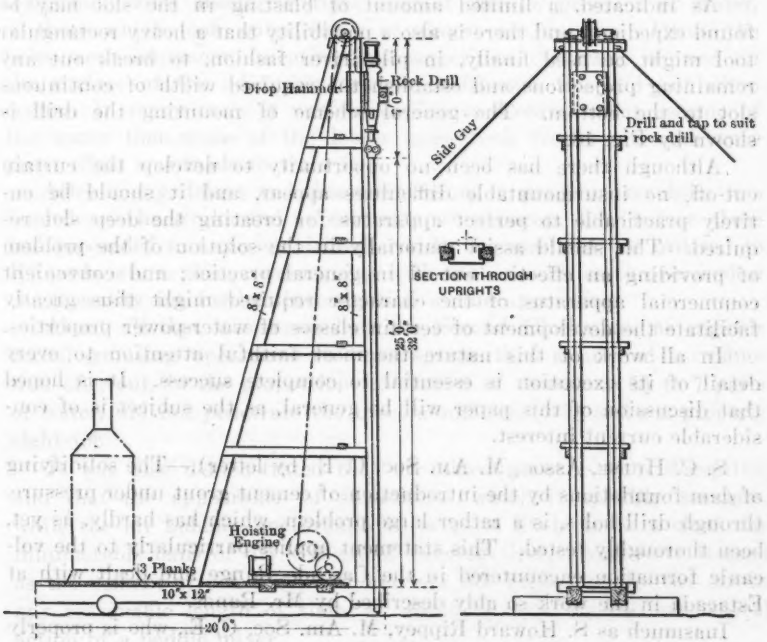

FIG. 18.

ings may require some experimentation to secure the best results, but one method which suggests itself is illustrated in Fig. 17, Sketch 3. Two standard wrought-iron pipes, having an outside diameter of $5\frac{9}{16}$ in. and perhaps 5 ft. long, are indicated, with the lower ends covered by a close-meshed wire netting which will pass water, but not cuttings. These tubular buckets, supported by chains with their tops just below the lower limit of stroke of the broaching bit, would collect almost all the cuttings, being raised and emptied when full. This would leave about 5 ft. at the bottom of the holes which could not be treated in this manner, but a shorter pair of buckets might be used at the

Mr. Rippey.

bottom, and the final cuttings might be washed out as completely as possible.

Another method considered, although probably more expensive and less favorable for the rapid action of the broaching bit, is illustrated in Fig. 17, Sketch 4. This involves placing temporary pipe casings in two adjacent drilled holes to guide the broaching tool and prevent its cuttings from dropping into the clean, drilled holes. In this plan the broachings from the web would be washed to the surface by a water jet in the same manner as in the drilled holes; a few trials should determine the most effective method.

As indicated, a limited amount of blasting in the slot may be found expedient, and there is also a possibility that a heavy rectangular tool might be used finally, in pile-driver fashion, to break out any remaining projections and establish the required width of continuous slot to the bottom. The general scheme of mounting the drill is shown by Fig. 18.

Although there has been no opportunity to develop the curtain cut-off, no insurmountable difficulties appear, and it should be entirely practicable to perfect apparatus for creating the deep slot required. This should assist materially in the solution of the problem of providing an effective cut-off in general practice; and convenient commercial apparatus of the character required might thus greatly facilitate the development of certain classes of water-power properties.

In all work of this nature the most faithful attention to every detail of its execution is essential to complete success. It is hoped that discussion of this paper will be general, as the subject is of considerable current interest.

Mr. Hulse.

S. C. HULSE, ASSOC. M. AM. SOC. C. E (by letter).—The solidifying of dam foundations by the introduction of cement grout under pressure, through drill holes, is a rather large problem, which has hardly, as yet, been thoroughly tested. This statement applies particularly to the volcanic formation encountered in the Cascade Range and dealt with at Estacada in the work so ably described by Mr. Rands.

Inasmuch as S. Howard Rippey, M. Am. Soc. C. E., who is properly accredited by Mr. Rands as the originator of the plan to grout a cut-off curtain across the (Second Clackamas) site several miles above Estacada, will doubtless take part in the discussion of this paper, the writer will confine himself rather to certain practical aspects of the grouting problem.

When the writer went to Oregon for Mr. Rippey in the fall of 1909, he had been given clearly to understand that his work at the Second Clackamas was to be very largely of an experimental nature. Mr. Rippey dwelt at length on the fact that his ideas (as generally expressed in the extract from the paper by Mr. Schreiber on page 10*

* *Proceedings*, Am. Soc. C. E., for January, 1914.

of the paper) dealt with something yet to be proven, and he, in spite of his strong belief in the ultimate result, insisted that his own attitude toward the results of the experiments to be made, would be most conservative. Mr. Hulse.

The experiments at the Second Clackamas were halted (by the postponement of the work for business reasons) before any positive results were obtained, as regards the actual efficiency of grouting. Somewhat more than 5 000 lin. ft. of core-drill holes were put down, and these ranged from 40 to 250 ft. in depth. Many and exhaustive pressure tests were made in these holes, and they ranged, from a few which were absolutely tight against 200 lb. pressure of water, to those which took water freely at almost no pressure. Often the holes were intercommunicating and sometimes the water showed on the surface of the adjoining territory—although this did not often occur. In many cases it was impossible to discover what became of the water that some of the looser holes took freely, although very great effort was made to trace it.

After many delays and disappointments, a grouting machine was landed on the work, and experiments were begun, but, before these had proceeded to any very definite result, the machine was ordered to Estacada where things were going with such a rush as to overshadow the necessity for further investigation at the upper site.

About all that was learned at the Second Clackamas, as regards actual grouting operations in breccia, was that a hurried introduction of grout, in the proportions of from 1 of cement to 1½ to 7 parts of water, did not penetrate the breccia sufficiently to make a properly tight job.

It was also demonstrated that air-mixed grout is very deceptive, and that the appearance of smoothness which it speedily assumes, while the air bubbles up through it, is quite likely to be a cloak for innumerable balls of dry cement of varying sizes, which have formed as the cement struck the water and are not broken up by the air in any reasonable length of time, as would be done by the mechanical action of a paddle mixer.

The openings in breccia range from the tiniest of pores into which cement may only be forced, if at all, with the greatest care, but through which water under high pressure will find its way, to cracks and cavities of considerable size. Any one who has had experience in cleaning the valves of a grout machine which has become plugged with a ball of dry cement under pressure may readily realize the facility with which badly mixed grout may close entrances to openings and thus prevent them from being properly filled.

The writer's experience with surface leaks at the upper site had not been encouraging, up to the time the experiments were discon-

Mr. Hulse.

tinued, but, on subsequent work, he has learned how to handle these, as will be detailed later.

To proceed to the conclusions arrived at on page 36* of the paper:

(1) The advisability of a concrete cut-off wall under the foundation of a dam is open to serious question, and the writer has heard more than one able and experienced engineer declare against the practice. To put in such a cut-off, a trench must first be opened. If this is done by hand, in any material capable of bearing a great dam, the work is likely to be slow and costly. If it is done by blasting, and particularly in breccia, where the use of a channeler is said to be impracticable because of the nature of the material, there is great danger of doing almost irreparable damage to the surrounding material, and this is exactly what happened in the left channel at Estacada, where the breccia adjoining the heel-trench was shaken and cracked in all directions by the blasting. The writer believes that grouting, properly done, may be used as a satisfactory substitute for a concrete cut-off, and to the top of the foundation rock.

(2) The testing of drill holes is such a fascinating pursuit (and the writer speaks from experience) that it may easily be carried beyond the limits of practical usefulness. However, the tank method is quite preferable where much testing is to be done.

(3) This method of procedure might readily entail an almost prohibitive amount of shifting about, and, if carried to its logical conclusion, might even lead to a complete and wholly unwarranted interruption of the grout and drill work. More will be said about this in connection with Conclusion (5).

(4) This conclusion is very true, and emphasizes the desirability of a grouting machine which may be operated by water pressure instead of by air. The following of water into the hole, behind the grout, would not be objectionable, whereas the air is a nuisance, and has to be closely watched, in this respect. The writer has hopes of developing such a grouting machine.

(5) and (3) There are two sorts of grouting which may be accomplished: plugging, and sedimentation or silting. There are several ways of going after subterranean territory, through the medium of a drill hole, in the hope of making that territory impervious to the passage of water under pressure, and the writer wishes now to present the method which seems to him best suited to the penetration of every opening of sufficient size to admit cement particles in the form of grout. This method is practically irrespective of the nature of the rock to be grouted.

The first necessity is a reliable driller, who realizes his responsibilities and will enter into the spirit of things. Fortunately, such drillers are not the exception, although one does occasionally meet with

* *Proceedings*, Am. Soc. C. E., for January, 1914.

an experience such as has been mentioned by Mr. Rands in connection with his search for cement in the cores. Mr. Hulse.

Casings should be set beyond the possibility of their coming loose. If this is impossible—as is sometimes the case in soft breccia—a mat of concrete, preferably to be incorporated later in the main structure, may be laid on top of and well bonded to the rock surface, at or near the heel line, and the casings set in this mat. The mat should be as narrow as possible, so that it will not close any more surface leaks than necessary.

If a core drill is used, the loss of drill water or the striking of a seam or crevice is the best indication of the time to test the hole. If a percussion drill is used, it may be well to test at stated depths—say, every 10 ft.—because the evidence of what is encountered by a percussion drill is not nearly so reliable as in the case of a core drill.

The point is that leaks should be grouted as soon as encountered. This is for the purpose of closing openings which would let the pressure out of the lower portions of the hole (yet to be drilled) were they not closed. In the absence of special equipment for testing purposes, charges of air or water blown through the grouting machine will answer perfectly well to indicate how freely the hole may be expected to take grout, and to show up any leaks on the surface.

The first grout introduced should be quite thin—say, 1 part of cement to 30 parts of water—and it should be absolutely free from lumps of any sort. Pressure should be applied gradually, and the instant a surface leak shows, the pressure should be dropped to such a point that only water (perhaps colored with cement) flows from the leak. This is the starting point for a successful closure of that leak by a process of sedimentation, as contrasted with the possibility of plugging it immediately by using thick or lumpy grout. From this time forward it is a matter of patience and of judgment in the application of pressure and the thickening of the mixture, and a great deal of patience is worth a very little thickening, as judged by the final results. Cement is never wasted by this process of "slow grouting" as long as it does not appear at the surface, and a careful nursing of the pressure will deposit the cement underground where it is wanted. In time—sometimes very quickly—the leak fills, and, as the resistance increases, more pressure is applied, until finally the hole refuses at the maximum pressure available. An exploration of many surface leaks thus "slow grouted" under the writer's direction, has disclosed the fact that they had been tightly filled with cement, and so very tightly as to preclude any subsequent opening due to shrinkage, as would have been the case had they been merely filled with the thickest grout that could have been run through them.

There is nothing in this sort of treatment to preclude the almost immediate washing out of the drill hole (after refusal) and the con-

Mr. Hulse.

tinued, but, on subsequent work, he has learned how to handle these, as will be detailed later.

To proceed to the conclusions arrived at on page 36* of the paper:

an experience such as has been mentioned by Mr. Rands in connection with his search for cement in the cores. Mr. Hulse.

Casings should be set beyond the possibility of their coming loose. If this is impossible—as is sometimes the case in soft breccia—a mat of concrete, preferably to be incorporated later in the main structure, may be laid on top of and well bonded to the rock surface, at or near the heel line, and the casings set in this mat. The mat should be as narrow as possible, so that it will not close any more surface leaks than necessary.

If a core drill is used, the loss of drill water or the striking of a seam or crevice is the best indication of the time to test the hole. If a percussion drill is used, it may be well to test at stated depths—say, every 10 ft.—because the evidence of what is encountered by a percussion drill is not nearly so reliable as in the case of a core drill.

The point is that leaks should be grouted as soon as encountered. This is for the purpose of closing openings which would let the pressure out of the lower portions of the hole (yet to be drilled) were they not closed. In the absence of special equipment for testing purposes, charges of air or water blown through the grouting machine will answer perfectly well to indicate how freely the hole may be expected to take grout, and to show up any leaks on the surface.

The first grout introduced should be quite thin—say, 1 part of cement to 30 parts of water—and it should be absolutely free from lumps of any sort. Pressure should be applied gradually, and the instant a surface leak shows, the pressure should be dropped to such a point that only water (perhaps colored with cement) flows from the leak. This is the starting point for a successful closure of that leak by a process of sedimentation, as contrasted with the possibility of plugging it immediately by using thick or lumpy grout. From this time forward it is a matter of patience and of judgment in the application of pressure and the thickening of the mixture, and a great deal of patience is worth a very little thickening, as judged by the final results. Cement is never wasted by this process of "slow grouting" as long as it does not appear at the surface, and a careful nursing of the pressure will deposit the cement underground where it is wanted. In time—sometimes very quickly—the leak fills, and, as the resistance increases, more pressure is applied, until finally the hole refuses at the maximum pressure available. An exploration of many surface leaks thus "slow grouted" under the writer's direction, has disclosed the fact that they had been tightly filled with cement, and so very tightly as to preclude any subsequent opening due to shrinkage, as would have been the case had they been merely filled with the thickest grout that could have been run through them.

There is nothing in this sort of treatment to preclude the almost immediate washing out of the drill hole (after refusal) and the con-

Mr. Hulse.

tinuance of the drilling to the next point where grouting may seem advisable. Holes grouted with thick grout will frequently take more grout, if re-tested within a few hours after the first refusal at maximum pressure, but it is very exceptional when one succeeds in making any impression whatsoever in re-testing a hole which has been "slow grouted" as just set forth. In the first case, the openings are plugged with a mixture which subsequently shrinks; in the second case, they are silted full so tightly as to preclude shrinkage.

As an illustration of the results to be gained by patience, the writer once grouted for eight continuous days and nights on a hole that took somewhat more than 200 tons of cement. For several days, thin grout was literally poured into that hole—much of it by gravity—and the grout was kept thin until the hole showed signs of closing up. Had Conclusion (5), as stated by the author, been followed, the operation would doubtless have ended much sooner, but the result (the hole, thus far, has proved to be tight against a head of 130 ft.) might have been quite different. Incidentally, of the more than 200 tons of cement used, perhaps a dozen sacks were wasted through the leaks which developed—surely not a high price to pay for placing where it was wanted the rest of the quantity used.

There is good evidence that Portland cement sets very slowly—if at all—after it has been introduced underground in this fashion, but, should the process of grouting necessarily entail an assumption of the necessity for the setting of the cement used? Rather should it not be looked on as an enforced closing of openings or passages by the silting or sedimentation of an insoluble material, introduced under an ultimate pressure greater than any which might subsequently tend to dislodge it? If the cement does set up, so much the better.

If the suggestion of the author, in connection with the grouting done at Estacada, that: "* * * so far as this job is concerned, that over a portion of the cut-off no grouting was needed, and that over those parts where it was needed it did little good", is to be sustained, what of the 1 920 bbl. of cement that were used? It is hardly to be assumed that all this cement went to close the cracks opened by the blasting of the heel-trench and to waste in dealing with surface leaks. That portion of the 1 920 bbl. which was not used for these two purposes must have gone somewhere in the foundation and have closed openings which would much better be closed than left open—else, why grout, or why bother about cut-offs? The action of the two test holes which were drilled inside the dam and flowed water, as set forth by the author, indicate obviously enough that the grout as applied did not close the breccia tightly, or, that the water passed under the curtain and then rose; and the writer is strongly inclined to the former view of the matter, but does not feel that the evidence in the case is to be viewed as damaging to the grouting system of tighten-

ing foundations. Rather, he believes that the Estacada work shows remarkable results in favor of the system. We have here, in the beginning, a case of a conservatively worked out scheme which is to be based on experiment and subject to experimental proof. Before anything much has been learned from the experiments, they are interrupted and a practical application is made, and under circumstances by no means favorable to a fair trial. Aside from the blast-shattered area which complicated the situation, the grouting work at Estacada was continually interfered with and hustled about, and hurried beyond the possibility of proper conduct, by the exigencies of rush construction; and, in the opinion of the writer, the engineers in charge of the grouting did remarkably good work under the circumstances. If, as the author states, no leaks of consequence have been observed below the Estacada Dam, may not a certain amount of credit be given to that part of the 1 920 bbl. of cement which was not wasted in handling surface leaks, and is it not conceivable that, had the work been less rushed, and had greater care with the grouting been possible, the flow in the test holes inside the dam might have been less? Mr. Hulse.

Grout work is likely to be at a disadvantage when brought into conflict with the man whose sole idea of the conduct of work is to set a new record for depositing a given quantity of concrete in the shortest possible time. For the grouting, there is little in evidence but a few small pipes—which may or may not connect with an underground opening which might, later, imperil the integrity of the concrete man's work, when the reservoir fills—and these small, insigficant pipes may even get in the road of the concrete man's buckets, and otherwise become very much of a nuisance.

If, therefore, it is possible to do the grouting and get the pipes out of the way before the beginning of actual construction, so much the better. If the grouting and construction must be carried on simultaneously, every effort should be made to keep them from interfering with each other; but, in case they must conflict, it seems rather superfluous to point out that, inasmuch as the integrity of the whole job will depend to a very great extent on the success of the grout work, the latter should be given at least "an even break" in the matter of precedence. An open cut-off trench, by its very presence, compels respect and consideration, but a line of 2-in. grout pipes, which may be expected to accomplish cheaper and better results than the cut-off trench, must frequently be aggressively guarded by the man in charge of them.

In any case, it is desirable that provision be made for drilling and grouting after the completion of the work, should later developments show the need for this later work. Usually, this may be done more at the cost of foresight than at the cost of trouble and expense.

The author's suggestion about the drilling of a row of holes close

Mr. Hulse. together and then broaching them into an open slot which may then be grouted, is open to the objections against blasting in the foundation material under the heel of a dam to be. If, however, this might be accomplished without damage, the writer would suggest that, before the holes are broached, they should first be carefully grouted so as to silt up the adjoining territory, and thus reinforce the thin solid cut-off to be made by filling the slot. Further, it would be most desirable, in filling the slot, to do so by introducing the grout at or near the bottom of the slot, and forcing it to rise slowly toward the surface. A succession of such operations, to be accomplished in a deep slot, by a gradual raising of the grouting pipes, would probably insure the tightest filling of the slot with the least chance of subsequent shrinkage and cracking of the material deposited therein. Without some reinforcement, which might be very difficult to place in a thin wall like this, the writer would not consider the scheme except in connection with a careful silting up of adjoining territory by first grouting the holes, as has been stated.

As a general proposition, the writer believes that the silting up of a foundation by grouting and by the action of the water impounded behind the dam, offers possibilities distinctly preferable to those of the conventional cut-off wall. In the case of a clear stream, like the Clackamas, it is usually practicable to make the water muddy by dumping or sluicing into it material from the banks, while the reservoir is filling, and thus close many or all of the openings missed by, or too fine for, the grout. The practice of shooting into foundation material under the heel of a dam is more than likely to make a lot of trouble—witness the left channel at Estacada—and the penetrating qualities of cement grout, properly handled, are very great. If the rock is good, why replace it with a concrete cut-off? If the rock is bad, and yet so solid as to necessitate blasting for its removal, how much better to silt it tight and leave it undisturbed?

Mr. Fisher. FRANK R. FISHER, ESQ. (by letter).—In the writer's final report as Resident Engineer in charge of the construction of the Estacada Dam, he stated, in discussing the grouting of foundations, that an impervious cut-off was not accomplished, that is, to the absolute degree had in view when the method was adopted. The varying and erratic nature of the formation made the solution of the problem largely experimental and one that could only be worked out by a thorough trial and without any positive assurance as to what the final outcome would be.

The writer does not consider that the method should be condemned or judged by the failure to obtain absolute tightness in the very peculiar material with which the engineers had to deal, but rather that credit should be given them for reducing the possibility of seepage to the extent that practically no uncertainty regarding the

safety of the foundations in that respect would remain. That this was accomplished, and the foundation material benefited by the treatment, he believes an analysis of the results, as stated in his report, will show. Mr. Fisher.

Mr. Rands arrives at the following conclusion: "that over a portion of the cut-off no grouting was needed, and that over other parts where it was needed it did little good." The first part of his statement is correct, in that over a considerable portion of the right channel and island sections, the average formation was found to be in good condition, not absolutely tight, but developing only a low rate of seepage under test. Naturally, this evidence was not apparent until it was disclosed eventually by the progress of the work, and then, in view of the ever-present uncertainty, due to the fact that occasional points would develop unexpected weakness, it was deemed advisable to follow out the original plan to completion. In the light of final knowledge acquired from the complete data obtained, it was evident that the grouting could have been omitted over certain stretches, and the number of holes on these sections materially reduced.

The remaining section, that across the left channel, is evidently what Mr. Rands refers to as: "other parts where it was needed it did little good". There was no question as to the need of some kind of treatment in this particular locality, as the material, from the standpoint of permeability, was the worst met with on the site of the dam. The water-pressure tests gave high rates of seepage, communication existed between holes located over a considerable distance, and also with the surface as many as 70 ft. from the point of testing. The holes took grout freely and, in the aggregate, several hundred barrels of cement were forced into the seams and crevices existing throughout the rock. As the individual seams were apparently of little width, the large quantity of grout taken would seem to indicate that it was diffused over a wide area.

Although the tests on the final proving holes, at the full depth of 50 ft., developed considerable seepage, it was very much less than the original. The most encouraging feature, however, was the very satisfactory results obtained for the first 30 ft. Over a length of cut-off of 70 ft., the aggregate of the seepage through thirteen holes, spaced approximately 6 ft. apart, when tested under a hydrostatic head slightly in excess of that created by the dam, was only 0.2 sec-ft., and it should be noted that this seepage was obtained by boring into the vitals of the foundations, and opening up and subjecting to direct pressure all points of weakness intercepted by the thirteen holes. It should also be kept in mind that this test was made on what was originally the weakest section of the entire cut-off.

It is also obvious that the test conditions were much more severe than could occur normally from the pond pressure, and, therefore, it

Mr. Fisher. is reasonable to conclude that the grouted cut-off is effective for a depth of 30 ft., and as this is reckoned from the bottom of an overlying 10-ft. concrete wall, the total effective cut-off is 40 ft.

As to the choice between a concrete and grouted cut-off for this depth, it is only necessary to point out that the high cost, difficulties of construction, and the element of time required—of vital importance in this case—would practically prohibit the use of concrete.

Evidence of the satisfactory final condition of the foundations was furnished subsequent to the completion of the dam and the filling of the pond by a thorough examination of the surface of the rock inside the dam, and the unwatered bed of the river immediately down stream. No springs or seepage could be observed, with the exception of a few very slight indications along the side of the left bank, and it is more than likely that these were from surface drainage.

The foregoing facts may not offer indisputable proof that the final satisfactory condition of the foundations was entirely due to the merits of the grouting treatment, but the evidence is in its favor, and it is entitled to all the credit that the results seem to warrant.

Mr. Coburn. H. L. Coburn, M. Am. Soc. C. E. (by letter).—Mr. Rands is to be congratulated on the thorough manner in which he has presented the problem and attempted solution in the matter of the cut-off under the Estacada Dam. The information contained in this paper will be of great interest to the Profession. There is little which can be added to Mr. Rands' statements, and the writer thoroughly agrees with his conclusions as to this particular structure.

In such a foundation as was found in Estacada it seems that the only reason for making extraordinary efforts to secure an impervious cut-off at great depth would be for the purpose of saving water, and that it was not at all necessary to prevent undermining, as the rate of flow through this foundation was so slow as to be negligible. If, however, some further protection was deemed necessary, the writer believes that the concrete cut-off could have been carried very considerably deeper than was done for a lesser sum than was expended on the grouting, and with much more definite assurance of success. If, in addition to this concrete cut-off, a carpet of fine silt, either of clay or volcanic ash or other fine material—which is present in large quantities—had been sluiced into the river bed and against the dam and extending several hundred feet up stream, it would appear certain that a very satisfactory seal would have been obtained. Indeed, the writer is confident that the natural deposit of silt which is inevitable in such a pond will seal this structure very completely, and in a comparatively short time.

Mr. Cushman. William H. Cushman, M. Am. Soc. C. E. (by letter).—The general scheme had been adopted and some of the earlier drilling accom-

plished at the time the writer took general charge of the project. The execution of this portion of the work, as already determined, became a duty, regardless of an individual lack of confidence in the ultimate successful accomplishment of the end in view. Mr. Cushman.

That the foundation material was sufficiently good to carry all the pressure to which it could possibly be subjected, will be conceded by all engineers familiar with the designs for the dam and the foundation material.

Although the breccia was porous, it was substantially free from open cracks, and it was scarcely to be considered a case where the percolation of water through the foundation material would result in undermining the dam.

Admitting these two propositions to be true, it would seem that the only practical consideration would be the one mentioned on pages 35 and 36* of the paper, that is, whether the water lost by percolation would be valuable enough to justify the cost of the grouting work.

Although the Clackamas is a clear-water stream, undoubtedly some silt depositing could be depended on, and possibly selected materials could have been deposited in the pool above the dam to assist materially in silting up the porous material.

Throughout the paper (as mentioned on page 20, the seepage test detailed on page 22, and again on page 28,* where serious thought of discontinuing grouting was entertained), considerable skepticism is expressed as to the effectiveness of the method of treatment. The quoted opinion of the author, that "Over those parts where it was needed it did little good", will be commonly agreed with, and cause little surprise to those who have had similar problems to solve.

The suggestion mentioned on page 37,* that the rock between the rows of drill holes be shattered with small charges of powder, originated with the writer, and it still seems that such shattering might have facilitated the flow of "thickened grout" and made it possible to restrict the treated area to the immediate vicinity of the cut-off wall, rather than diffuse it to remote points by subjecting it to the heavier pressure required to force it through small openings.

It would be interesting to know whether an attempt has ever been made to shatter a trench through rock, to a depth of as much as 50 ft., and then introduce grout or thin mortar (fed through pipes from the bottom and flowing upward or otherwise) in such manner as to produce, in effect, a concrete wall to the depth stated. It would not seem impracticable to accomplish this, and do away with surface capping with concrete and the use of excessive pressure.

Considerable thought and investigation were given by Messrs. Rippey, Fitzgerald, Schreiber, and the writer, to various methods of cut-

* *Proceedings*, Am. Soc. C. E., for January, 1914.

Mr. Cushman.

ting an open trench or seam through the rock to the required depth, in order that an impervious curtain could be introduced. Special channeling machines, drill holes closely spaced and then broaching out the material between holes, and even open cut, were considered. It would be of interest to hear from engineers who have accomplished something along these or similar lines.

Mr. Rands is to be commended for the painstaking manner in which he has presented this interesting subject, and, though it be admitted that the procedure was, to a large extent, futile, nevertheless, his subsequent work has proven the value of this first experiment.

MEMOIRS OF DECEASED MEMBERS.

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

ERNEST PONTZEN, Cor. M. Am. Soc. C. E.*

DIED OCTOBER 13TH, 1913.

Ernest Pontzen was born at Budapest, Austria-Hungary, on January 20th, 1838. He obtained his early engineering education at the Polytechnic School of Vienna. In 1856, he went to Paris and entered the French engineering school, l'Ecole Nationale des Ponts et Chaussées, as an "Externe" student, and was graduated in 1860 at the head of his class.

After a study trip in England, Mr. Pontzen returned to Austria-Hungary, and filled various positions in connection with the railways and harbors of that country. He was Consulting Engineer to the Anglo-Austrian Bank for 4½ years, and, in that capacity, directed the construction of several railway lines, made a study of various railway projects, and became the Director of a railway company in Hungary.

In 1873 he made his first study trip to the United States. He made a second trip in 1876, to serve as member of the Jury in the Railway Group at the Philadelphia International Exposition. Returning to Paris, he established himself there permanently, and eventually became a naturalized French citizen. He married Miss Hirtz, daughter of the distinguished physician and professor of that name, of the University of Strassburg, who survives him.

Mr. Pontzen was the author of numerous publications dealing with the construction and operation of railways. His most important work, issued in collaboration with Mr. Lavoinne, and entitled "American Railways," was published in 1880-82, the first volume dealing with the construction and cost of railways, and the second with their operation.

Mr. Pontzen served on various important commissions. He had been a member of the Government Commission for the technical exploitation of railways since 1884, almost from its inception. Acting in this capacity, he was one of the delegation which represented the French Government at the International Conference for the promotion of technical uniformity on railways, and more recently he was a delegate of the Minister of Public Works to the International Railway Congress at Washington, and, later, to that at Berne.

* Memoir prepared by Charles L. Strobel, M. Am. Soc. C. E.

He was also selected as an expert and arbitrator in very important cases, such as the Loetschberg Tunnel, the Harbor of Varna, the acquisition of the Algerian East, and the Cé Bridge accident.

He was a Member of the Council on Instruction (Conseil d'Instruction), and of the Council on Betterment (Conseil de Perfectionnement) of l'Ecole Nationale des Ponts et Chaussées.

Mr. Pontzen was a Past-President of the Society of Colonial Engineers and Past Vice-President of the Society of Civil Engineers of France. He was one of the founders and, up to the time of his death, was President of the Friendly Society of "Externe" Graduates of l'Ecole Nationale des Ponts et Chaussées. He was also an officer of the Legion of Honor and a Commander of various French and foreign orders.

This brief outline of Mr. Pontzen's career will indicate that it was fruitful in engineering achievement and rich in well-merited honors. He went to France as a stranger, and died in the country of his adoption, having won not only the esteem of Frenchmen, but to a singularly high degree their love and affection.

Mr. Pontzen spoke French, German, English, Italian, and Hungarian, and with foreign engineers whom he met at Congresses, he was able, therefore, to converse in their mother-tongue. All who met him in this way remember him most pleasantly for his uniform courtesy and cheer. American engineers who had the good fortune to know him were always sure of a cordial welcome at his hands, and he freely gave them of his time and attention in the promotion of their interests or their comfort and pleasure. He was the kindest, most considerate, and most devoted of friends. It may be said of him that the conduct of his life was so noble and inspiring, that the highest tribute will be paid to it that can come to any man, in that it has left the desire, especially on the part of the younger men, to emulate his example as best they can.

Mr. Pontzen was elected a Corresponding Member of the American Society of Civil Engineers on January 5th, 1876.

ARTHUR LINCOLN ADAMS, M. Am. Soc. C. E.*

DIED SEPTEMBER 17TH, 1913.

Arthur Lincoln Adams, son of Jacob Clendennin and Nancy McCoy (Hamilton) Adams, was born on September 15th, 1864, on a farm near Greensburg, Ind. He was a lineal descendant of John Adams, who came to Plymouth Colony, Massachusetts, in the ship, *Fortune*, in 1621.

* Memoir prepared by Franklin Riffle and W. A. Cattell, Members, Am. Soc. C. E., and A. Kempkey, Assoc. M. Am. Soc. C. E.

When about eight years of age he moved with his parents to Topeka, Kans., where the family resided for a period of about three years, and then returned to Indiana. In 1882, soon after the death of Mr. Adams' father, the widow again moved with her children to Topeka, where she resided during the remainder of her life.

In his early boyhood Mr. Adams attended the district schools of Indiana, and the public schools of Topeka. Later, he entered the Greensburg High School, from which he was graduated in 1882. He was a student at Hanover College, Ind., in 1882-83, and Washburn College, Topeka, Kans., in 1883-84.

During the summer of 1883 he was in the employ of the County Surveyor of Shawnee County, Kansas, and assisted in surveying in and about Topeka. During the following summer he was with a surveying party engaged in subdividing Government land in Southwestern Kansas. Starting as a Chainman, he was promoted to Transitman before the close of his engagement. When the survey was completed, each member of the party was requested to state, under oath, that the work had been done correctly, to the best of his knowledge and belief. Being somewhat in doubt as to the accuracy of the survey, Mr. Adams, together with several others of the party, strenuously objected to being sworn. At this juncture, one of the youthful mutineers made the discovery that Quakers were permitted to affirm in lieu of taking oath, whereupon Adams insisted that the same privilege be accorded him and his conscientious associates. His arguments prevailed, the affirmations were duly made, and all the members of the party were given honorable discharges.

In the fall of 1883 students of the State University of Kansas started a movement to organize a State oratorical association, to affiliate with the Interstate Association. Mr. Adams was a delegate from Washburn College to the constitutional convention. He took a prominent part in the proceedings, which resulted in the organization of a State association, and was active in arranging for the first contest. He participated in the trial and settlement of a famous case of plagiarism which developed in that contest.

In 1884 he became a student in the Engineering Department of Kansas State University, and was graduated in 1886. At a public rhetorical recital he read a humorous essay entitled "The Philosophy of Selfishness", in which his theories and conclusions were so extreme as to create a sensation among his hearers. Only a few of the audience appreciated the undercurrent of humor which pervaded the essay, or realized that the extreme views advocated by the speaker were purely for rhetorical effect.

During the spring of 1886, he obtained employment in the Engineering Department of the Burlington and Missouri River Railroad, in Nebraska, in the office of one of the resident engineers, and was soon

promoted to Division Engineer on Construction. In this position he displayed unusual efficiency, originality, and judgment, for one of his age and experience.

During the summer of 1887, he concluded to try his fortune on the Pacific Coast. He accordingly accepted a position as Leveler in a location party on the Oregon Pacific Railroad. When the party was disbanded, during the following winter, he went to Southern California in search of employment and spent several months in Los Angeles.

During the spring of 1888 he returned to the Pacific Northwest to accept a position as Assistant Engineer on Construction, offered him by the Chief Engineer of the Oregon and Washington Territory Railway, now a part of the Northern Pacific System. In this position he had an excellent opportunity to observe and study the wonderful resources of Eastern Oregon and Washington. He was quick to grasp the significance of the development of this vast inland empire, and to see with prophetic eye the varied and multitudinous engineering problems to which this development would give rise. Many thriving towns were in various stages of development, and some of them had already reached a point where the necessity for sewer and water systems was occupying the attention of their citizens.

Up to this time, Mr. Adams, like many other young engineers, had followed the lines of least resistance. He had become a railroad engineer through force of circumstances. After graduation he had accepted a position on a railroad because it was the only position immediately available. Municipal engineering, however, was his choice, and he now determined to make a start in this field. The Town of Pendleton, Ore., had recently created the office of "City" Engineer, and the Mayor was given the appointing power. Before resigning his position as railroad engineer, Mr. Adams discussed the matter with the Chief Engineer, who accepted his resignation with regret, but, nevertheless, co-operated with him in his efforts to secure the coveted municipal position. Mr. Adams was successful in obtaining the appointment, at the same salary he had received from the railroad. In conducting the negotiations which terminated so happily, he exhibited that remarkable business sagacity which contributed so largely to his later successes. Foreseeing that as "City" Engineer of a small town his duties would not be very onerous, he stipulated that he should be granted the privilege of performing such private work as he might see fit to undertake during his term of office. He prepared a contract fully covering this phase of the question, and it was duly signed by the contracting parties. It was not long, however, before his private practice assumed such large proportions that he found it advisable to resign.

In 1890 Mr. Adams prepared plans and specifications for a system of water-works for the Town of Dayton, Wash., and superintended its

construction. During the following year he performed a similar service for Colfax, Wash.

In the summer of 1891 he entered into partnership with his brother-in-law, Robert C. Gemmell, M. Am. Soc. C. E., under the firm name of Adams and Gemmell. The new firm designed and superintended the construction of water-works for La Grande, Ore., and Waitsburg, Wash. They also designed a water system for Heppner, Ore., and a water-power plant at Kalama, Wash., neither of which was constructed, however, owing to the financial panic of 1893. The firm did considerable miscellaneous surveying in Oregon and Washington, including two large irrigation canals on the Umatilla River, Oregon, one on the Walla Walla River, Washington, and one on Eagle Creek, near Baker City, Ore. The construction of these canals was indefinitely postponed by the "panic". They prepared plans and specifications for a water-works system for Athena, Ore., and a sewer system for Montesano, Wash., both of which were constructed, although not under their supervision.

During the fall of 1893 Mr. Adams made a very complete report on an increased water supply for Astoria, Ore., and recommended the construction of a new system. His report was adopted in its entirety by the Board of Water Commissioners, and Adams and Gemmell were authorized to make the necessary surveys and plans. Before the completion of the preliminary surveys, the partnership was dissolved, and the work was continued by Mr. Adams, who, as Chief Engineer, carried it through to a successful termination—less than 3 years after having made his preliminary report. An admirable description of this work was written by Mr. Adams, under the title, "The Astoria City Water Works".* This paper won for its author the Thomas Fitch Rowland Prize for 1897. In his paper he described quite fully an ingenious device (of his own invention) for opening and closing two fire gates from a central station; this being accomplished "by opening and closing an ordinary stop-cock at the end of a line of ordinary ¾-in. service pipe leading to a patented governor attached to each of the gates."

During the construction of the Astoria Water-Works (1895), Mr. Adams prepared a report on a new water system for Eureka, Cal., and on the character and probable cost of the private works then supplying the city. After the completion of the Astoria Water-Works, he opened a consulting office in San Francisco. During 1897 he prepared plans and specifications for the reconstruction of water-works at Centralia, Wash., and also reported on projected new works for Lakeport and Oceanside, Cal.

From 1897 to 1900, he held the dual position of Manager and Chief Engineer of the West Los Angeles Water Company and the West Side Water Company. During this period he resided in Los Angeles, where

* *Transactions*, Am. Soc. C. E., Vol. XXXVI, p. 1.

he also carried on a consulting practice. As Chief Engineer of the two Los Angeles Water Companies, he was called on to plan and construct extensions in order to keep pace with the steadily increasing demand. He constructed a 5 000 000-gal. reservoir, and a pipe line to the Soldiers' Home, Santa Monica. In connection with the pipe line, he designed an ingenious weir and gate device for maintaining a definite delivery under varying conditions of pressure.

During this period Mr. Adams filled various engagements, among which were the following:

He was a member of a commission of engineers engaged by the City of Los Angeles to determine the value of the improvements made to the water-works of that city during the 30 years' lease by the Los Angeles City Water Company; he was a member of a commission of engineers engaged by the City of Pasadena to appraise the several water-works used for the supply of that city; in conjunction with J. B. Lippincott, M. Am. Soc. C. E., he reported on sources of supply and plans for an entirely independent system of water-works for Pasadena; he developed a water supply and prepared plans for its utilization, in the irrigation of a large ranch near Corona, Cal.; he prepared a report outlining plans, and giving estimates of cost, for a combined municipal water supply and power installation for Missoula, Mont.; he prepared plans and specifications for the reconstruction of the water-works of Pendleton, Ore.; he reported on the probable effect on the water supplies of the San Gabriel River, California, of the contemplated construction of certain power plants on that stream; he prepared a report on the value of the properties of the West Los Angeles Water Company and the West Side Water Company, as an aid in effecting a sale of these properties to the City of Los Angeles; he prepared a report and gave evidence concerning the value of the properties of the Contra Costa Water Company used for supplying the City of Oakland and its vicinity; and he prepared a report and gave evidence concerning the causes of an extensive land-slide which had for some years prevented the use of the large reservoir on the west side of the Willamette River, at Portland, Ore.

In 1901 Mr. Adams became Engineer and Manager of the Contra Costa Water Company, Oakland, after having been retained as an expert in the important litigation case which had just at this time been concluded.

The case was the now famous one known as the Hart case, and was instituted to enjoin the City of Oakland from enforcing the rate ordinance enacted by the City Council. Although several other eminent engineers were engaged in the case, it was conceded by all that the clear and convincing testimony of Mr. Adams as to values, and his clear exposition of the theories of valuation, had more to do with the victory of the Company than any other one thing. The Company

was granted in effect an increase in rates amounting to 15%, and, although in later years engaged in many important legal matters, Mr. Adams often remarked that he considered this case the most important of its kind in his career.

Early in 1903, Mr. Adams resigned from the management of the Contra Costa Water Company and opened a consulting office in San Francisco, and from this time he continued steadily his consulting work. Although his practice was never such as to require a large organization, it was at all times of the highest type. Among the more important of his engagements may be cited that with the City of Victoria, B. C. His report dealt with the existing conditions and present and future needs, covering the subject in complete and exhaustive detail. Later, he prepared plans and specifications covering the then present needs, and, under his direction as Consulting Engineer, they were executed.

While still retaining his consulting practice, he was, in 1906, made Chief Engineer of the Department of Greater Water Supply of the Peoples Water Company, successors to the Contra Costa Water Company, supplying water to seven cities on the east side of San Francisco Bay. Complete preliminary studies and investigations were carried on by this organization looking to the more than doubling of the water supply of this Company. A complete comprehensive plan of future development was outlined, and construction was begun on the more important elements, but financial stringency prevented carrying out more than a small portion of this work.

Mr. Adams did a very large amount of valuation work, particularly of public utilities. Among the more important properties on which be reported may be mentioned the Peoples Water Company, the Spring Valley Water Company, the Palermo Land and Water Company, the Virginia and Gold Hill Water Company, the Petaluma Power and Water Company, and numerous others.

In 1909, he designed the irrigation system for the Patterson Ranch Company, at Patterson, Stanislaus County, California. This system provides a means for irrigating, by pumping, about 18 000 acres of land on the west side of the San Joaquin River in the San Joaquin Valley, and was at that time considered to be of unique design and the most extensive and complete system of the kind in the United States.

At the time of his death Mr. Adams was engaged in the construction of a plant similar in design to the Patterson Ranch system, but more elaborate as to details, for the irrigation of about 22 000 acres of land near Brentwood, Contra Costa County, California. He was also, at the time of his death, Consulting Engineer for the Peoples Water Company, and was engaged by this Company in important rate litigation pending in the Federal Court.

Mr. Adams was foremost among those who organized the San

Francisco Association of Members of the American Society of Civil Engineers. He was elected Treasurer of the Association for a term of 2 years, and became its third President in 1907. Immediately after the earthquake in 1906, he was instrumental in holding a series of special meetings of the Association, which resulted in a study of "The Effects of the San Francisco Earthquake of April 18th, 1906, on Engineering Constructions," by a general committee and six special committees composed of members of the Association, followed by extensive reports.* Mr. Adams was Chairman of the Committee on the Effects of the Earthquake on Water-Works Structures, and wrote the Committee's report.

Mr. Adams held a high rank both personally and professionally. He was exceedingly democratic in his ideas, very simple in his tastes, and exceptionally companionable. He possessed a keen, analytical mind that served him well in the litigation with which he was so frequently connected as an expert witness. He delighted in the legal subtleties of these cases no less than in the engineering problems involved. Although active in assisting and supporting the attorneys with whom he was associated, he always commanded the admiration and respect of the engineers and attorneys who opposed him. His ability was acknowledged and his work commended by friend and foe alike. His professional career was one of uninterrupted achievement from its beginning to its untimely end. Long before his death he had attained a foremost place in the ranks of the leading hydraulic engineers of the Pacific Coast. He possessed in a marked degree the rare combination of professional skill and business acumen which enabled him to procure for his clients the best attainable results at a minimum cost. Having early in his career established a reputation for efficiency and integrity, he thereby created a demand for his services, for which, usually, he was able to name his terms. While always fully alive to his personal interests, he never for a moment overlooked the interests of his profession. He continuously sought to uphold its dignity, and to educate the public to a proper conception of its importance as a factor in the world's development. On numerous occasions he fearlessly exacted from his clients the recognition to which he believed his profession was entitled.

Mindful of his early struggles for recognition, he strongly sympathized with young engineers, and was ever ready to extend a helping hand to those in need of assistance. It was largely the desire to aid the younger members of the profession that induced him to take a prominent part in the organization of the San Francisco Association of Members of the American Society of Civil Engineers. He believed that they, more than the older members of the Society, would be benefited by membership in this organization. During the practice of his

* *Transactions*, Am. Soc. C. E., Vol. LIX, p. 208.

profession he gave employment to many young engineers. He invariably treated his subordinates with forbearance and tolerance, and thus secured and retained their respect, loyalty, and friendship.

Mr. Adams possessed a gift which, unfortunately, is quite rare among engineers—that of clear, terse, forceful expression. This applied to his speech no less than to his writing. Whether writing a report, explaining an engineering proposition to a client, elucidating a technical point while on the witness stand, or addressing an audience, he invariably chose his words well, and without hesitation. In argument he was convincing and rarely failed to carry his point. Whenever he took a stand for or against a proposition, he gave the impression of being master of the situation. He never allowed himself to be swerved from the course which his conscience or his judgment marked out.

His energy and ability, however, were not devoted entirely to his engineering practice. He was a zealous and efficient worker in the cause of religion and morality. He was prominent in the affairs of the church of which he was a member, and also gave much of his time and resources to the Young Men's Christian Association and Young Women's Christian Association of Oakland. The Y. M. C. A. Building, and the new First Presbyterian Church edifice, both in Oakland, are to a very large extent the results of his effective work.

Mr. Adams was a well-read man. He was especially fond of poetry. Among the poets, Robert Burns was his favorite. He occasionally wrote verse of a serious nature, although not for publication. One of the writers of this memoir has in his possession several of Mr. Adams' poems, one of which, entitled "A New Year's Revery", possesses exceptional merit.

Frank T. Oakley, M. Am. Soc. C. E., who was a classmate of Mr. Adams in the public schools of Topeka and in the State University of Kansas, and also was associated with him during his professional career, writes of his life-long friend as follows:

"He was always very tolerant of the beliefs of other people, never seeming to wish to force his opinions upon others. However, when it came to argument, few could hold their own against him. My observation leads me to believe that he always followed a thoroughly digested plan of conduct and business from which he did not allow himself to vary in principle, and I believe much of his success in life's problems was due to this fact as well as to his unusually good judgment.

"Some time over twenty years ago, while sitting in camp, he outlined to me his idea of an engineering career leading up to a consulting business. When I came to live in California, I was impressed with the similarity of his outline of a career and his experience, and the way he carried on his professional business. He always insisted on giving any undertaking his best thought, and would not be identified

with it otherwise, not sparing himself hard work; and as a consequence he was always accorded a leader's place by his associates.

"I believe that Arthur L. Adams was the finest character I have ever known, and that it is not possible for me to know how much I owe to association with him. His influence was always for good and manly things. This feature did not eliminate, or in any way curb the mischievous or boyish spirit, or the joy in sport or in a practical joke, but it did eliminate any meanness—a thing that was impossible in his nature.

"In our close association, including two years of living together, I never knew him to be gushingly confidential. There was always something of a reserve about him. Nevertheless, I never knew one in whom I could more freely confide, and who was more ready with the best and most kindly and tactful advice. I knew him best during the character-forming age, when boys are fully themselves and freely open to their playmates. Yet I never knew him to do an act or express a thought that was not in accord with his later high moral and mental attainments. Nor was he in the least prudish, nor did his associates ever think of calling him a 'goody-goody boy.'

"During our college days we frequently discussed all kinds of subjects pertaining to human life and affairs. Whether the subject was a social matter, the mathematics of gambling, or theology, freedom and frankness of thought and expression were always the same, always tending to a greater and more beneficial knowledge of the subject and, in fact, a crystallization of one's own opinions. When thinking of Arthur Adams' character, I am reminded of what Riley makes the farmer say of his friend and neighbor:

> "'Fer the name of William Leachman and
> True Manhood's jist the same.'"

C. Derleth, Jr., M. Am. Soc. C. E., pays the following tribute to Mr. Adams, both as a man among men and an engineer:

"Through his writings, particularly on wooden stave pipe, I have known Mr. Adams by reputation at least since 1896. I did not meet him personally until 1904. But since then I feel that I have had an opportunity to know of his work and to appreciate his personality. For the last eighteen years I have worked for, or have met in various ways, a great many engineers whose names are prominent in our national societies, and these men hail from all quarters of the United States. I am convinced that among them none has combined in the highest sense, better than Mr. Adams did, all of those qualities which contribute to the professional and personal character of an engineering gentleman. One always associated with Mr. Adams the qualities of integrity, industry, wide reading, learning in fields other than engineering. He had a great command of the powers of speech. He wrote fluently. He was an engineer who used reason and who had powerful judgment. Above all, he was a man of the finest moral instincts. He was always ready to help improve the tone of engineers and to raise the standard of engineering ethics. Indeed, he applied the same qualities to wider fields and was a power for good and uplift in the community in which he lived. As more men like Mr. Adams

become identified with engineering, so in proportion will the community's respect for the profession of engineering increase."

Augustus Kempkey, Assoc. M. Am. Soc. C. E., writes of Mr. Adams as follows:

"As his Principal Assistant for some eight years immediately preceding his death, the writer came to know Mr. Adams as a most refined and courteous gentleman of the highest type, every ready to give the best that was in him to the uplift of humanity and to the assistance of those around him. His thoughts were ever on the highest plane and his judgment, particularly in engineering matters, remarkable to a degree that at times seemed little short of uncanny. His mind, working perfectly clear and along direct lines, enabled him to grasp the essentials of an engineering problem almost at once, and his solution of these essentials was equally direct and expeditious. His criticisms of and orders to his subordinates were always given in a most kind and considerate manner, and no matter what the subject, he was always ready to receive suggestions and ideas from those directly under him. In all my association with him, I never saw him either reject or accept a suggestion without being fully informed as to its significance and value; and in the case of rejection, pointing out clearly his reasons therefor, and if accepting, giving due praise and weight to the value thereof. In short, he was a man who inspired and encouraged ideas and suggestions from his subordinates, while withal he never provoked that familiarity which ultimately breeds contempt. In each of his reports it will be found that he never failed to give credit to those who had assisted him in their preparation.

"He believed the engineering profession to be one of the greatest, and maintained an ethical standard such as few can hope to measure up to. By the life and conduct of such men as he, the engineering profession will be raised to its highest plane, and the moral tone of all with whom they come into contact cannot fail to be enriched. With all who had the privilege of working with Mr. Adams, and with all who came into contact with him in any walk of life, his memory will live forever as that of a true gentleman and an eminent—or rather a pre-eminent—engineer."

Mr. Adams was married on December 18th, 1889, to Mary Gemmell, of Topeka, Kans., who, with two sons and three daughters, survives him. Robert, the eldest, is a student in the Engineering Department of Stanford University, and two of the daughters are students in the University of California.

Mr. Adams died at his home in Oakland, Cal., on September 17th, 1913, of pneumonia, after an illness of less than one week. In his death the Engineering Profession has lost one of its great leaders; the community an active and efficient instrument for civic and social betterment; and his family and friends a wise counselor and a genial, lovable companion.

Mr. Adams was elected a member of the American Society of Civil Engineers on October 2d, 1895. From 1907 to 1909 he served as a

Director. He was President of the San Francisco Association of Members of the American Society of Civil Engineers during 1907. He was a member of the Franklin Institute, the American Academy of Political and Social Science, the Technical Society of the Pacific Coast, the Pacific Association of Consulting Engineers, and of the First Presbyterian Church of Oakland. He held important offices in his church, and was Vice-President and Director of the Young Men's Christian Association of Oakland. He was also a member of the Delta Tau Delta and Sigma Xi college fraternities.

RICARDO MANUEL ARANGO, M. Am. Soc. C. E.*

DIED JANUARY 24TH, 1914.

Ricardo Manuel Arango, Consulting Engineer for the Republic of Panama, died at his home in the City of Panama, on January 24th, 1914, after a long illness. He was born on December 25th, 1864, and was graduated in 1887, with the degree of C. E., from the Rensselaer Polytechnic Institute, at Troy, N. Y. His first work after graduation was a survey, under the direction of the late Pedro J. Sosa, M. Am. Soc. C. E., a prominent engineer of Panama, of 500 000 hectares of land in the Province of Bocas del Toro, conceded by the Colombian Government to the French Canal Company. This party did the first surveying work in that region.

In 1889, Mr. Arango was appointed by the Colombian Government to take charge of surveys made necessary by a controversy between it and the Panama Railroad, over the filling of the present site of Colon. In 1890, he was engaged on the railroad which was built to haul to the coast the products of the manganese mines of Viento Frio, Province of Colon. He assisted in the surveys and plans for providing the City of Panama with water from the Juan Diaz River, but this development was never realized.

Mr. Arango took an active part in the Revolution of 1903 by which Panama secured its independence from Colombia, being of great assistance to his father, José A. Arango, who was a member of the original Junta of Separation. As member of the Municipal Council of the City of Panama, Mr. Arango signed the Act of Independence, and was appointed the first Chief Engineer of the new Republic.

Under John F. Wallace, Past-President, Am. Soc. C. E., Chief Engineer of the Isthmian Canal Commission, Mr. Arango was Consulting Engineer for sanitary work in the City of Panama. Later, he was made Division Engineer of the Bureau of Meteorology and

*Memoir prepared by Alex. P. Crary, Assoc. M. Am. Soc. C. E.

River Hydraulics. As head of this Bureau, he installed the first seismograph on the Isthmus, and established the gauging station at Alhajuela, on the Chagres River, from which advices of any floods could be telephoned in advance to those in charge of work on the lower reaches of the river. His services with the Isthmian Canal Commission were terminated in the fall of 1908. Soon afterward Mr. Arango was appointed Minister Plenipotentiary and Envoy Extraordinary for the Republic of Panama to the Court of St. James, which post he was compelled to relinquish in 1909 on account of ill health. In 1910, he was again made Chief Engineer of the Republic, and, later, Consulting Engineer, which position he held at the time of his death.

He was a Member of the Instituto de Ingenieros de Chile, the Seismological Society of America, and the Sociedad de Ingenieros, Arquitectos y Agrimensores de Panama, of which latter he was the founder. On September 21st, 1899, he was married to Miss Maria Lewis, who, with five children, survives him.

Mr. Arango was a man who loved his profession. Even during his long illness, when he had lost almost completely the use of his hands, he took great delight in reading and studying engineering. In a wonderful manner he had trained his mind so that he could transform equations, construct graphical diagrams, and do things mentally which are generally accomplished by paper and pencil. He was always genial and willing to help and give advice. He stood up courageously under his sickness though it deprived him of the many pleasures and much work which make life worth living. He was always interested in public affairs, and, as long as he could, he took an active part in them. In his death, Panama loses one of its best and most progressive citizens.

Mr. Arango was elected an Associate Member of the American Society of Civil Engineers on September 2d, 1896, and a Member on February 6th, 1906.

JOHN WILLIS HAYS, M. Am. Soc. C. E.*

DIED DECEMBER 14TH, 1913.

John Willis Hays was born at Oxford, N. C., on March 14th, 1861, and was christened with the name borne by his father and his grandfather. He was educated at local private schools and the University of North Carolina.

As a young man Mr. Hays did engineering work under the late Benjamin D. Frost, M. Am. Soc. C. E., of Massachusetts, who had distinguished himself in connection with the building of the Hoosac Tunnel in that State, and was, at the time in question, engaged in laying out a route for the Oxford and Henderson Railroad. Later,

*Memoir prepared by Francis B. Hays, Esq.

Mr. Hays joined the field staff of William C. Kerr, State Geologist of North Carolina, where he acquired experience and developed ability which gained for him an appointment as a Topographer in the United States Geological Survey. This position he held for many years, first in the Appalachian Mountains, and later in the Rockies, during the summer, and at Washington in winter.

In addition to the remarkable thoroughness of his engineering work, Mr. Hays was distinguished for the unusual excellence of his drafting. Indeed, his artistic ability was marked, and had he chosen Art as a vocation, his success would doubtless have been gratifying. Nor was his facility with the pen confined to drafting and free-hand sketching, for many of his exciting mountain adventures were reduced to manuscript and published in such periodicals as *The Outing Magazine, The Youth's Companion,* and the newspapers of Washington and other cities. He was also an occasional contributor to journals devoted to engineering matters.

Leaving the Government service in the early Nineties for work in which his individuality would have freer play, Mr. Hays became City Engineer of Petersburg, Va., having a few years previously married the daughter of one of the leading citizens of that place, who, with a large family, survives him. While in that position he laid out Ferndale Park, constructed the high-service reservoir, and in other ways left his impress on the city's physical characteristics.

Mr. Hays' nature was such that he could not be contented in a political position. He knew of but one course to pursue, and that was the one of absolute rectitude as he saw it, and he was remarkably free from moral strabismus. Consequently, he left the public position to engage in private work. Although frequently urged to return to the City Engineership at an increased salary, he steadfastly and politely declined.

In the meantime, he built up a private practice which became more remunerative as the years went by, and he was able to command the fee of an expert for a mere opinion. Shortly before his death, he had completed the development of the Walnut Hills Section, reached from the City of Petersburg proper by an iron viaduct over a broad gorge which latter had long rendered it practically inaccessible. He developed the water power at Roanoke Rapids, N. C., and did municipal work at Mt. Airy, Dunn, Kingston, and other towns in his native State, as well as at Emporia, Blackstone, and many other points in the State of his adoption.

Physically, Mr. Hays was a man of magnificent mould, having been considerably more than 6 ft. in height, erect and clean-limbed, and carrying his two hundred and odd pounds without the suggestion of a surplus ounce of flesh. He was cut down at the zenith of his powers by thrombosis induced by a fall sustained while engaged in field work.

Mr. Hays was Master of Blandford Lodge of Masons, President of the Petersburg Benevolent Mechanics' Association, an Elk, and, for several years, had conducted with marked success a men's Sunday-school class. He was a man of vigorous mind, keen intellect, catholic tastes, strong personality, a faithful friend, and a true gentleman.

Mr. Hays was elected a Member of the American Society of Civil Engineers on June 5th, 1901.

LUTHER REESE ZOLLINGER, M. Am. Soc. C. E.*

DIED OCTOBER 21ST, 1913.

Luther Reese Zollinger, the fifth son of William George and Susannah (Spece) Zollinger, was born on April 25th, 1865, in Harrisburg, Pa. He received his early education in the public schools of his native city, having been graduated from the High School in 1883. Of his early life his most intimate boyhood acquaintance, Dr. C. R. Phillips, of Harrisburg, writes:

"No member of our class in High School, where we were associated for four years, held his classmates by the mere strength of a lovable personality as did Luther Reese Zollinger. We were all devoted to him because of that indescribable something he had, which, unfortunately, is uncommon, and made us certain of his sincerity of purpose and life. He was honor man in our class in High School, easily so too, and I have always felt that he was honor man in our class at Lehigh, though it is true that one or two others had a few per cent. higher standing, according to the poor, insufficient ratings which, as things educational stand, must still be taken to measure a man's mind and ability. Of all the men whom I have known, he had, I always felt, the best mind for mathematical work. In saying this I, of course, except a few neurotics whose mathematical ability always is a part of an unstable mental equilibrium."

In 1884, Mr. Zollinger entered Lehigh University, and was graduated in 1888 with the degree of Civil Engineer. He was President of his class in the Sophomore year, Editor of the College *Epitome*, and Business Manager and Editor of the *Engineering Journal*, and had a Commencement appointment. During his 4 years in college he never ranked lower than fifth, and for the last 3 years he ranked second in a class varying from 101 to 66 men.

Mr. Zollinger's entire professional career was spent in the service of the Pennsylvania Railroad Company, in which he rose by his own efforts and merit from the humble post of Chainman to the position of trust and responsibility which he occupied at the time of his death. Starting in the office of the Assistant Engineer, Middle Division, at Harrisburg, Pa., on March 11th, 1889, he received his first professional

* Memoir prepared by J. F. Murray and C. J. Parker, Members, Am. Soc. C. E.

experience at the time of the great floods throughout Pennsylvania, in May and June of that year, which proved so destructive to the railroads and other internal improvements in various parts of the State, especially in the vicinity of Johnstown, and along the Susquehanna, Juniata, and Connemaugh Rivers.

He held successively, and for varying periods from 1889 to 1905, the various positions of Transitman in the office of the Engineer of Maintenance of Way, Pennsylvania Railroad Division, at Altoona; Assistant to Assistant Engineer, Philadelphia Division, at West Philadelphia; Assistant Supervisor, Division No. 8, Middle Division, Pennsylvania Railroad, at Spruce Creek; Supervisor, Division No. 28, at Norristown; Supervisor, Division No. 1, Philadelphia Division, at West Philadelphia; Assistant to Principal Assistant Engineer, and Principal Assistant Engineer, Pennsylvania Railroad Division, at Altoona.

On April 1st, 1905, Mr. Zollinger was promoted to the position of Engineer of Maintenance of Way, General Office, Philadelphia, which position he held at the time of his death. In this capacity he was in charge and had direct control of the Maintenance of Way Department, in so far as was necessary to insure the efficiency of the Department and adherence to the standards of the Company. He also had charge of the preparation of all maintenance of way plans, the issuing of instructions in regard to adherence to the same, and personally examined all bridges and other structures, reporting on their condition and making recommendations in connection therewith, as well as with respect to other matters relating to maintenance of way.

In addition to these duties, Mr. Zollinger, in 1905-07, was in charge of the construction of extensive yards and yard facilities at Morrisville on the New York Division, and at Shire Oaks on the Monongahela Division; he was also appointed as Chairman of various committees, by the General Manager, to make experiments, investigations, and reports on sundry matters relative to the economical construction and maintenance of track. One of these reports,* dated March, 1911, covers extended experiments to determine the necessary depth of stone ballast. Of this report, W. C. Cushing, M. Am. Soc. C. E., Chief Engineer, Maintenance of Way, Pennsylvania Lines West, says: "These tests are the most extensive of the kind ever conducted in this country, and will be found of great interest and value to railway engineers."

Mr. Zollinger traveled extensively, both in this country and in Europe, and his wonderful powers of observation, retentive memory, quick comprehension, enthusiasm, and capacity for work, made him invaluable to the company he served. As an example of his enthusiasm and wonderful resourcefulness, he purchased a tract of land at

* *Proceedings*, American Railway Association, Vol. 18.

Merion, Pa., on which was an old, abandoned stable, and with the aid of his architect transformed it into a beautiful home of the English manor type,* utilizing for the interior finish and decoration the materials from an old mansion formerly on the estate.

His personality was peculiarly lovable and attractive, and left its impress deep on all who met him. One felt immediately that he was a man worth knowing, an impression that association only strengthened and confirmed. Big of body, handsome of feature, with great magnetism, his winning personality drew all classes of men to him, and he held them with hooks of steel by his genial, broad-minded, and tolerant disposition. He was by nature a man of essentially social tendencies. Of fine intellectual gifts, broad education, wide acquaintance with the best literature, discriminating taste in the fine arts, varied experience with many classes of men, an observant traveler, with a retentive memory, great fund of anecdote and reminiscence, and a keen sense of humor, he was always entertaining in conversation. These qualities, with his loyalty, kindness, generosity, and buoyance of spirits, made him a most interesting and delightful companion.

Full of sympathy, he was never too busy to give time to the troubles of his friends or counsel to the youth seeking opportunity. It is not often that a man who has attained high professional standing shows a live interest in the young man just beginning his life work, but Mr. Zollinger was the champion of youth, with an unbounded faith in its capabilities and the fulfilment of its aspirations. This faith he exemplified in a very striking and practical way, for he took more than one young man into his home, gave them his friendship and confidence, inspired them by his manliness, educated them at his own expense, and launched them on honorable and useful careers in life. It was a great satisfaction and source of much pride to him to know that each of these young men fully justified the trust placed in him.

His genial nature, overflowing with good fellowship, so attractive to his many friends, was carried into his domestic circle and was one of the finest phases of his life, as seen by his intimate friends. He never married, and his devotion to his sister can only be described as beautiful. Nothing he did for her was ever felt to be a sacrifice. His happiness was only reached through her happiness. Such affection was warmly reciprocated, and his home was made to him a place of charm as well as of rest.

Mr. Zollinger's dominant characteristic was courageous and vigorous manhood. His power of mind and body was shown in his capacity for concentration and the accomplishment of work. He was of quick discernment and swift comprehension, and his strength made him positive in his convictions and strenuous in maintaining them. With

*Described by the architect in *House and Garden*, December, 1912.

his strong character and self-respect, he could never play the courtier, and he detested to receive the flattery he would never apply to others, not even in the form of studied deference which, at times, might have gained him personal advantage.

Enthusiasm in regard to whatever matter he took up, either work or recreation, was another feature of his character, and made him a natural leader. He was a lover of the beautiful in Nature and art. Nature in all her forms appealed strongly to him. Some of his happiest hours were spent in roaming among the trees of the forest or the flowers of his own garden, whose characteristics and history he knew so well. He kept in touch with the advancement in science and all questions of the day, and could enjoy intelligently and appreciate intercourse with men versed in many forms of learning.

Men of great professional attainments and mental power are often deficient in those qualities of the heart which make them loved as well as honored, but these qualities Mr. Zollinger possessed in an unusual degree. He had intellectual superiority, and he was a man of honorable achievement, but those who knew him well think of him and love him for his broad-gauged, liberal-minded, vigorous manhood and spotless integrity. He was chivalric in thought and deed, and the courteous gentleman always. Honor, truth, and duty were the stars by which he steered his course, and in him was embodied the highest type of manhood. Of splendid physique, clean and wholesome morals, a fascinating personality with a highly cultivated mind, he died in the prime of brilliant achievements. The exquisite charm of his friendship can be known only to those who enjoyed it; to them it was a benediction, and his death an irreparable loss. In a generation we shall not see his like again.

Mr. Zollinger had complained of ill health for several months prior to his death, though he did not relinquish any of his work, and had just returned from the annual track inspection when he was stricken with apoplexy, on the morning of October 16th, and died at his home in Merion, Pa., on October 21st, 1913.

He was a Member of the American Railway Engineering Association and the Delta Upsilon Fraternity.

Mr. Zollinger was elected a Member of the American Society of Civil Engineers on March 6th, 1901.

MURRAY FORBES, Assoc. M. Am. Soc. C. E.*

DIED DECEMBER 28TH, 1913.

Murray Forbes was born in Philadelphia, Pa., on June 23d, 1863. His father, Dr. William S. Forbes, was Professor of Surgery at Jef-

* Memoir prepared by W. C. Hawley and G. W. Hutchinson, Members, M. Am. Soc. C. E.

ferson Medical College. His mother Celinere (Sims) Forbes, was a sister of J. C. Sims, Secretary of the Pennsylvania Railroad Company, and Judge Clifford Sims of the Superior Court of New Jersey.

Mr. Forbes received his early education at Rugby Academy and at Dr. Farries' School, in Philadelphia, and entered the Art School of the University of Pennsylvania at the age of fourteen. When he was 17, he entered the Pennsylvania Railroad shops at Altoona, Pa., where he took the regular 4 years' apprenticeship course. He was then employed in the shops for some months, being afterward transferred to Derry, Pa., where for 4 years he was Assistant Road Foreman of Engines on the Pittsburgh Division of the Pennsylvania Railroad.

He resigned this position in 1888 and went to Greensburg, Pa., where he took charge of the construction of the plant of the Westmoreland Water Company. Mr. Forbes continued as the executive head of this Corporation until his death. Under his direction, the plant was extended and, with allied corporations, served the communities along the Main Line of the Pennsylvania Railroad west from Greensburg as far as Irwin, and south along the Southwest Branch as far as Youngwood. A total of 50 000 people are supplied, in addition to large industrial and mining plants, by the companies in which he was the guiding spirit, and this, too, in a section where, because of the broken topography and the dumping of mine drainage into the streams, the operating conditions are exceedingly difficult and expensive. Mr. Forbes was in responsible charge of the design and construction of the plant, and, at the time of his death, he was, and had been for many years, Manager, Secretary, and Treasurer of the Company and its allied interests.

Mr. Forbes' success at Greensburg resulted in his being chosen to take charge of the construction and operation of water plants for the Derry Water Company at Derry, Pa., and the Dennison Water Supply Company at Dennison, Ohio, serving as Manager, Secretary, and Treasurer of both these corporations. He also had a large financial interest in all three companies.

Mr. Forbes was recognized as an authority in matters pertaining to water-works construction, operation, and valuation. He was employed in a number of water-works cases, either as an expert witness or as a member of boards of arbitration. He assisted in organizing the Pennsylvania Water Works Association and served for 3 years as its President. He was also a Member of the American Water Works Association, the New England Water Works Association, the Engineers' Society of Western Pennsylvania, the Engineers' Society of Pennsylvania, and the Union League Club of Philadelphia. He was a Mason and a member of the Protestant Episcopal Church.

Mr. Forbes was a delightful character, always kind and courteous, a man who made friends readily and who kept them. Of strong convictions, he was also a diplomat. Although for many years he had acted as Manager of the Water Company which served the town in which he lived—and under difficult conditions and with necessarily high rates—he was popular and highly respected in that community. An editorial in a Greensburg newspaper, at the time of his death, reads, in part, as follows:

"Mr. Forbes was in many ways superior. He was a factor in the affairs of his town and of his county. He was intensely human. He was a master of his profession, and he controlled because he knew. A useful man has been taken from this community."

In 1893, Mr. Forbes was married to Miss Ethel Parvin, of Philadelphia, who, with five children, survives him.

Mr. Forbes was elected an Associate Member of the American Society of Civil Engineers, on June 5th, 1907.

THE DETERMINATION OF SAFE YIELD OF UNDERGROUND RESERVOIRS OF THE CLOSED-BASIN TYPE

By Charles H. Lee, Assoc. M. Am. Soc. C. E.

To be Presented May 6th, 1914.

Summary and Conclusions.

The objects of this paper are to show the possibility and practicability of measuring the annual rate of recharge of underground reservoirs of the closed-basin type, and to indicate broadly the factors which determine safe yield from a basin by artificial development, such as Artesian flow or pumping.

The paper opens by pointing out the importance of the problem in California and the Southwest. Following this there is a description of the physical features of underground reservoirs and the general principles of inflow, outflow, and storage. The body of the paper presents detailed methods and results of extended measurements, by the Los Angeles Aqueduct Bureau and the United States Geological Survey, for the determination of the rate of annual recharge of the Independence Basin, in Owens Valley, California. The subjects of percolation from stream channels, relation of precipitation and altitude, soil evaporation combined with transpiration from grass, and ground-water fluctu-

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

ations, were carefully studied in the field, and original data are presented. The paper closes with a discussion of the relation which the net safe yield from a basin bears to the rate of annual recharge.

The conclusions are as follows:

1.—The "underground reservoirs" of California and the Southwest are water-tight rock basins, represented by the topographic valleys, which are filled with porous alluvial material in which the voids are saturated with water.

2.—Inflow into these basins is by percolation from water on the surface of the alluvial filling, which source may occur as direct precipitation, stream flow, irrigation, or flooding. Natural ground-water loss occurs in the region of lowest depression of a basin, and consists of the breaking out of water at the surface in springs or seepages, evaporation from soil, transpiration, and underflow. Artificial development, by wells or other methods, reduces the natural ground-water loss. Considered as averages, the rates of recharge and ground-water loss are equal, unless the artificial draft is excessive.

3.—The rate of recharge in a region of small precipitation and high evaporation rate can be determined most accurately, and with least expenditure of time and money, by measuring the elements which make up the ground-water loss. Of the natural elements, the most important are soil evaporation and transpiration. The underflow is relatively small and often negligible.

4.—The safe yield of artificially developed ground-water obtainable from an underground reservoir is less than indicated by the rate of recharge, the quantity depending on the extent to which soil evaporation and transpiration can be eliminated from the region of ground-water outlet.

Introduction.

There are in California and the arid States of the Southwest many valleys underlaid by porous alluvial material in which the voids are filled with water. The ease with which water can be developed from wells in these valleys and the definite bounds of the water-bearing formation have led to the use of such terms as "underground lake," "underground basin", or "underground reservoir". These terms are in general use among local hydraulic engineers, and have been adopted by the California Courts in numerous recent decisions pertaining to the use of diffused percolating water occurring in closed basins.
